These congenital anomalies arise from incomplete development of the posterior cricoid lamina and trachea-esophageal septum. The midline defect can be of varying length and this tends to correspond to the severity. Laryngeal clefts are associated with trachea-esophageal fistulas in 25% of cases. They are also associated with many syndromes including Opitz-Frias and Pallister-Hall.[76–78] The length of the cleft corresponds to the severity of symptoms. The main symptom itself is aspiration, but this can be a simple cough with some feeding difficulties to severe cases of frank aspiration coupled with cyanosis or respiratory distress. In children presenting with a history of aspiration, there should be a high index of suspicion for a laryngeal cleft.

Diagnosis and classification of a laryngeal cleft is made at MLB (Video 18.1). The interarytenoid area must be carefully visualized and palpated for the presence of a cleft. There are several classification systems for laryngeal clefts, but perhaps the most commonly used and simplest is as follows:

Type 1—interarytenoid cleft down to and including the vocal cords
Type 2—extension into cricoid cartilage
Type 3—extension through cricoid into cervical trachea
Type 4—extension into intrathoracic trachea

Contrast studies, such as barium swallow and video fluoroscopy, will demonstrate a cleft and the aspiration. The severity of symptoms and the cleft itself will determine the treatment with surgical repair of laryngeal clefts reserved for symptomatic children:

## Type 1 Clefts

Conservative management of interarytenoid clefts should be the initial choice, with swallowing therapy particularly aimed at thickening feeds to prevent aspiration. If this fails, endoscopic repair is advocated.[79] Through a laryngoscope, the mucosa is cut from the inner margins of the cleft, which are then sutured together (Fig. 18.16).

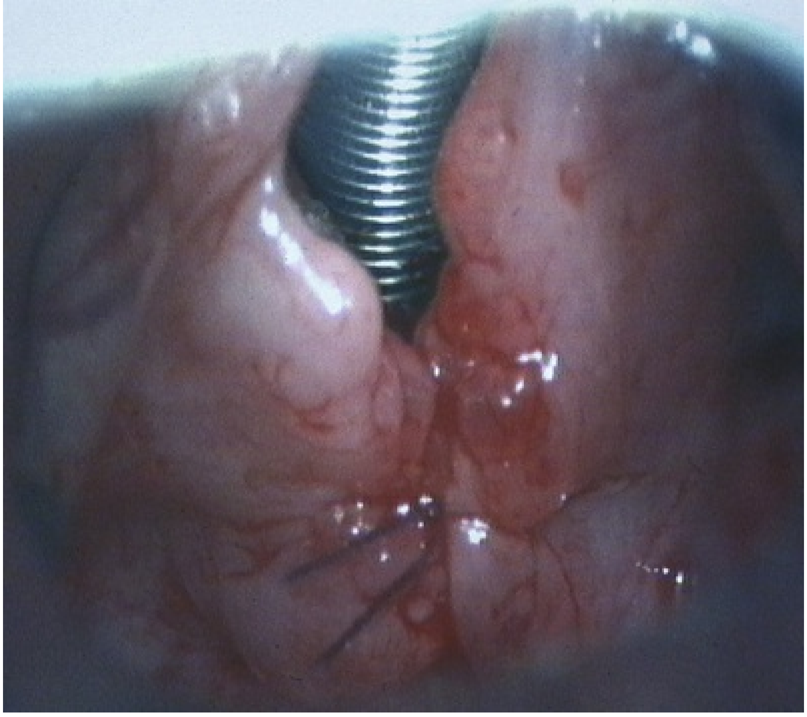

**FIG. 18.16** Endoscopic repair of laryngeal cleft type 1.

## Management of Type 2 and 3 Clefts

Some smaller Type 2 clefts may be easily closed with an endoscopic technique,[79] but for more extensive defects there are difficulties of access and instrumentation and late breakdown of the repair.[79,80] Open procedures are advocated for Type 3 clefts and usually involve an anterior approach, as this avoids damage to the recurrent laryngeal nerves. A vertical laryngo-fissure is performed and the cleft is closed with either direct suturing with consideration of an interposition of a fascial graft. A tracheostomy may be necessary if prolonged postoperative ventilation is anticipated, but with shorter clefts 7–10 days of postoperative intubation may suffice to stent the surgical segment.[81]

### Management of Type 4 Clefts

Type 4 clefts include two very different prognostic outcomes from surgical repair.[82] The total group carries a 50% mortality but in cases where there is no carinal structure; that is, a true carinal cleft, there are no reported survivors from surgical reconstruction. Where there is an intact carina repair the thoracic segment via sternotomy or thoracotomy with or without the use of cardiopulmonary bypass is very difficult. If the tracheoesophageal folds are very basic, it may be necessary to close off the esophageal sphincters and to use the whole of the undivided foregut as the airway. Because treatment entails significant morbidity and mortality, the decision on whether to operate should be based upon the associated comorbidity and fully informed parental choice.[83] These children will need continued input from the speech and language therapy service in the postoperative period.

## Vocal Cord Paralysis

Vocal cord palsy is the second commonest congenital anomaly of the larynx and can be bilateral or unilateral. Unilateral lesions are more common on the left, due to the longer course of the recurrent laryngeal nerve, and generally due to a nonfunctioning peripheral nerve. Other causes of unilateral palsy include peripheral nerve pathology, mediastinal lesions, such as tumors, vascular malformations, or thoracic surgery. Bilateral palsies are associated with lesions of the central nervous system, including Arnold-Chiari malformation, hydrocephalus, meningoceles, and myasthenia gravis. Birth trauma is often the cause for transient cord palsies, and these can be bilateral or unilateral.[84,85]

Vocal cord palsy can vary tremendously in its presentation as the functional impairment can vary from minor feeding difficulties and voice issues to severe respiratory distress that may warrant tracheostomy. Classically, there is inspiratory stridor and a weak cry, and this is the usual case with unilateral palsies. In older children dysphonia and exertional dyspnea may be the presenting symptoms. In cases of bilateral vocal cord palsy, stridor associated with respiratory distress is the predominant feature, and the presentation can be at a birth.

Awake FNE allows for dynamic assessment of the vocal cords and often clinches the diagnosis. Naturally, the procedure can be technically difficult in some cases, but with experience this can often be managed and lead to a clear diagnosis. Video recording of the procedure can prove invaluable in difficult cases. Ultrasonography of the vocal cords is relatively noninvasive and growing in popularity. With continued experience, the sensitivity and specificity of this technique is likely to improve. Other radiological modalities imaging the full length of the recurrent laryngeal nerve, specifically MRI, should be arranged to exclude intracranial causes and CT scanning to exclude compressive causes in the neck or thorax. Laryngeal electromyography is not commonly employed but may be useful in monitoring function and recovery. MLB should be performed in these patients which can additionally confirm the diagnosis as it includes dynamic assessment but it allows for other pathologies to be excluded, particularly cricoarytenoid joint fixation and posterior glottic stenosis.

Unilateral cord palsy can usually be managed conservatively, although speech and language therapy input is often vital to combat issues related to voice and feeding. Bilateral cord palsy can present with neonatal airway distress requiring intubation followed by tracheostomy. However, if the child is carefully monitored, tracheostomy may be avoided in 50% of cases.[86] Underlying causes should be treated to allow for resolution of the paralysis. Idiopathic cases certainly exhibit resolution in about 70% of cases, and this can be as late as a decade on from diagnosis. Tracheostomy decannulation can be achieved following resolution of the paralysis, but it is also often sought when the paralysis is likely to be permanent. Any surgical intervention to aid decannulation must take into consideration the possible adverse effects on laryngeal function related to voice, airway, and aspiration risk. The techniques that can be considered to aid decannulation include cordotomy, arytenoidectomy, and suture lateralization.[87] Open or endoscopic posterior laryngeal grafting techniques have also been employed, as have laryngeal reinnervation procedures.

## Saccular Cysts and Laryngoceles

The saccule is a blind ending structure that opens into the laryngeal ventricle, the lateral space between the true and false vocal cord. It runs in an anterior-superior direction and is usually of modest size in the normal larynx. It is lined by pseudostratified columnar epithelium and contains serous and mucous glands. A laryngocele is an abnormally enlarged laryngeal saccule and is air-filled. The condition is a rare congenital abnormality but may produce significant airway obstruction. It may be entirely within the confines of the larynx or extend into the neck via the thyrohyoid membrane. If the lesion is small, it may be excised using an endoscopic approach. Alternatively, an open operation may be necessary for larger lesions, with the possible need for a prior tracheostomy to ensure an adequate airway postoperatively.

Saccular cysts are mucous filled and are found in the false vocal cord or aryepiglottic fold (Fig. 18.17). They are presumed to arise from a part of the saccule that has become sealed off from its outlet into the ventricle. They may be massive and cause immediate and severe airway obstruction. Standard endoscopic therapy is aspiration and marsupialization with scissors or laser. There is a high rate of recurrence, and open resection may eventually become necessary.[88]

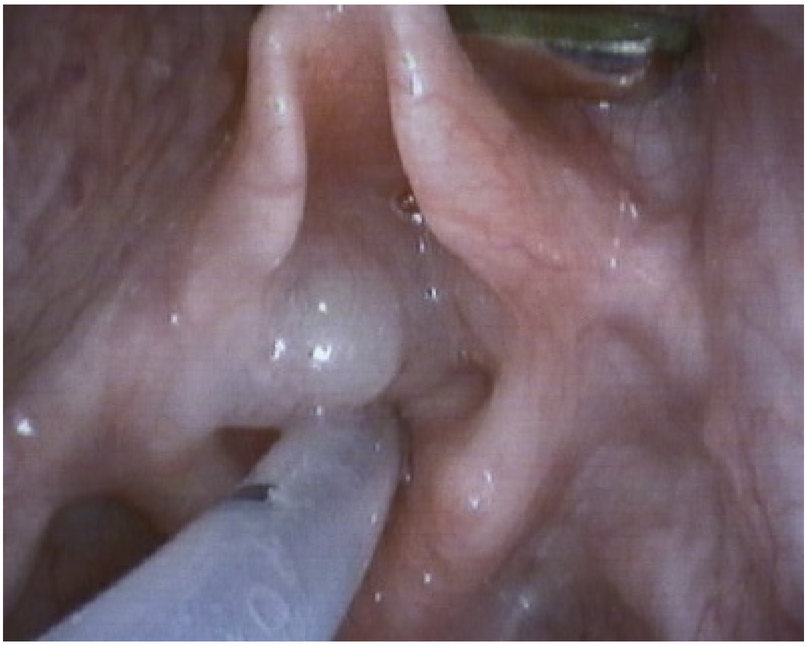

**FIG. 18.17** Congenital saccular cyst of aryepiglottic fold.

## Hemangiomas—Subglottic and Tracheal

Infantile hemangiomas are benign vascular tumors and account for 1%–2% of all congenital anomalies of the larynx. Similar to cutaneous hemangiomas, they have a natural history, which includes a phase of rapid growth and proliferation followed by phases of involution. They can occur at all sites in the airway but are rare; the subglottis is the most common subsite. They usually present with symptomatic airway obstruction in the first 3 months of life, and this condition manifests itself more commonly in females than males, at a ratio of 2 : 1.

Infants with subglottic hemangiomas present with stridor that is not characteristically present at birth. As the lesion grows, symptoms ensue and typically the child presents with biphasic stridor around the age of 6 weeks. Symptoms can deteriorate as the lesion grows in size and this can occur up until the age of 2 years when the lesion then reduces in size, as seen in many cases of cutaneous hemangiomas. Presentation may mimic croup, and, since the lesion transiently regresses with dexamethasone treatment, the diagnosis may be missed until there have been recurrent bouts of airway obstruction.[89] Infants with subglottic hemangiomas are likely to have a cutaneous lesion in 50% of cases. The need for treatment arises due to the growth of the subglottic lesion in a confined space, which inevitably gives rise to airway compromise.[90]

Again, the gold standard for diagnosis is MLB. This allows for exclusion of other pathologies as well as direct visualization of the lesion. Photo-documentation of the lesion allows subsequent MLBs to determine the response to treatment. The lesion is most often seen as a solitary entity posteriorly in the subglottis, although multiple lesions can occur and rarely, these can be located at the mid-tracheal level. The lesion itself appears as a soft, compressible, red mass. The neurocutaneous disorder, PHACES syndrome (posterior fossa brain malformations, hemangiomas, cardiac anomalies and coarctation of the aorta, and eye anomalies with or without sternal clefts) should be considered and ruled out in cases of subglottic hemangioma.[90–92]

In 2008, the treatment of hemangiomas was revolutionized by the serendipitous discovery of propranolol therapy.[93–95] Previous treatments had included systemic and topical steroids and surgical excision; these options are now secondary with propranolol therapy being the first-line treatment option. However, treatment with propranolol is protracted and needs careful monitoring for side effects, and dosages need to be adjusted over the treatment period, which can typically vary from 12 to 18 months, although it can be longer in some cases. Responses, as determined by MLB findings and symptoms, can be seen within a few days of commencing treatment (Fig. 18.18). A minority of patients does not show any improvement with propranolol therapy and may require traditional interventions, such as open or endoscopic debulking or resection of the lesion.

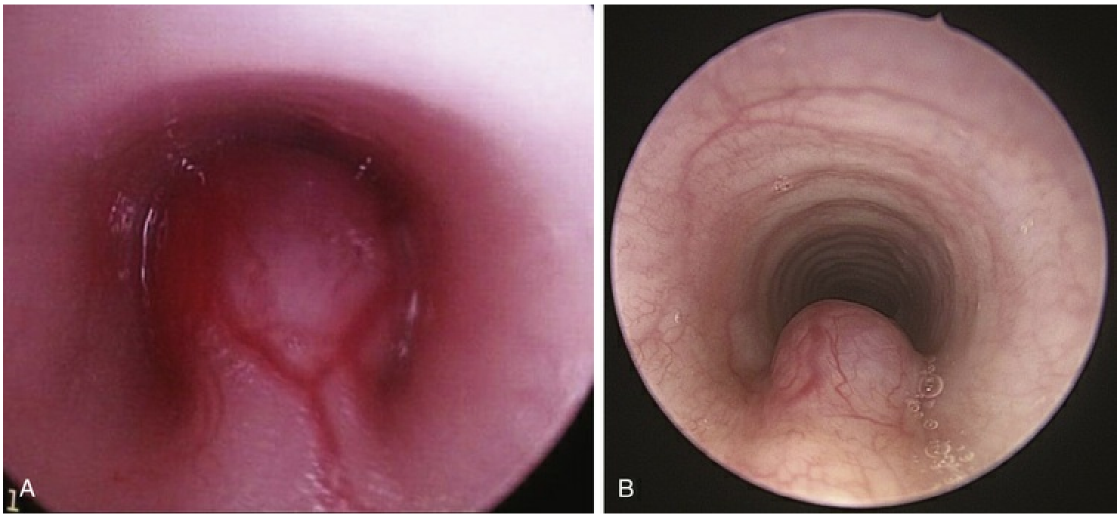

**FIG. 18.18** (A and B) Case of tracheal hemangioma prepropranolol and postpropranolol therapy (pictures 2 weeks apart).

## Congenital SGS

This is a relatively common congenital anomaly of, and the second most common cause of, stridor in infants.[96,97] The underlying pathophysiology of congenital SGS involves incomplete recanalization of the laryngotracheal tube during the third month of gestation. This can lead to varying degrees of stenosis, complete laryngeal atresia being the extreme form. There are two main types of congenital SGS. Membranous SGS is the result of circumferential submucosal hypertrophy with excess fibrous connective tissue and mucus glands. This type is the most common and milder form. Cartilaginous congenital SGS results from a deformity of the cricoid cartilage or entrapment of the first tracheal ring within the cricoid. The cartilage usually narrows laterally, but may also develop generalized thickening or growth of the anterior or posterior laminae.

Congenital SGS may not manifest itself until the first few months of life, typically when a child develops an acute inflammatory process/illness. Naturally, a severe stenosis may result in symptoms from birth. The stridor associated with SGS is characteristically biphasic in nature, and this may be present with varying degrees of respiratory compromise. In an acute illness, when the congenital narrowing is further compromised by an overlying inflammatory process, the presentation is typically that of a child presenting with laryngotracheobronchitis or croup. An underlying SGS should be suspected in all cases of recurrent or refractory croup. An additional scenario in which this condition should be suspected is one of difficulty in intubation or extubation in an otherwise asymptomatic child. Children with Down syndrome may also have an underlying congenital SGS.

The gold standard for diagnosis and classification of SGS is by MLB. Formal endoscopic examination of the airway allows for the diagnosis to be made and for other abnormalities to be excluded. The dimensions of the stenosis (length and diameter) can be assessed during endoscopy, and this is vital for any consideration of surgical repair. The lumen diameter can be assessed by passing appropriate-sized ET tubes—the largest tube that demonstrates a leak at normal ventilation pressures—and determining the degree of obstruction according to the Cotton-Meyer grading system:

Grade I: 0%–50% obstruction
Grade II: 51%–70% obstruction
Grade III: 71%–99% obstruction
Grade IV: No detectable lumen

Surgical correction, when indicated, takes the form of

1. Cricoid split, with our without interposition cartilage graft.
2. Laryngotracheal reconstruction (LTR). Rib cartilage is used to hold open a vertical slit in the cricoid and upper trachea, either in the anterior wall alone, or as separate anterior and posterior grafts.
3. Cricotracheal resection (CTR). The stenotic segment is excised with direct anastomosis of the airway. This is technically difficult when the stenosis involves the vocal cords.

A single-stage procedure is ideal (though not possible in all cases). Postoperatively, the child is intubated for 7–10 days prior to a trial of extubation. Airway reconstruction has been shown to have good outcomes, even in the presence of concomitant anomalies.[98–100] Balloon dilatation has also been described.[101]

# Congenital Abnormalities of the Trachea

## Tracheomalacia

Tracheomalacia is an abnormal collapse of the trachea during the respiratory cycle due to localized or generalized weakness of the tracheal wall (Fig. 18.19).[94,95] Microscopically, specimens show an increase in the ratio of muscle to cartilage. It is sub-divided into primary or secondary, though either form can be congenital. In primary tracheomalacia, there is an intrinsic abnormality of the tracheal wall, whereas in secondary cases there is extrinsic compression. In congenital cases, this is usually in association with cardiovascular abnormalities including the following (these are discussed in more detail in Chapter 39[102,103]):

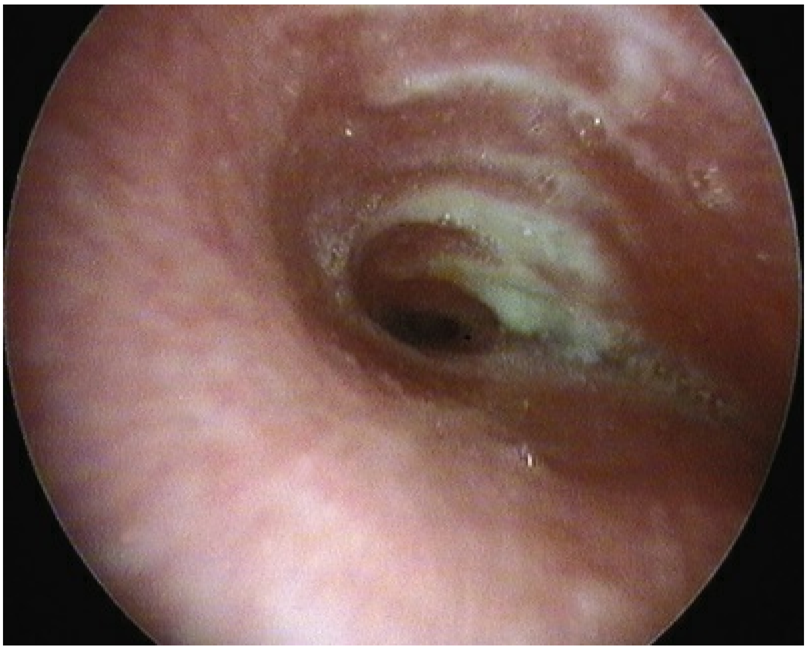

**FIG. 18.19** Tracheomalacia, which was acquired secondary to cardiac surgery.

1. *Double aortic arch*—surrounds the trachea, producing a concentric compression (Fig. 18.20)

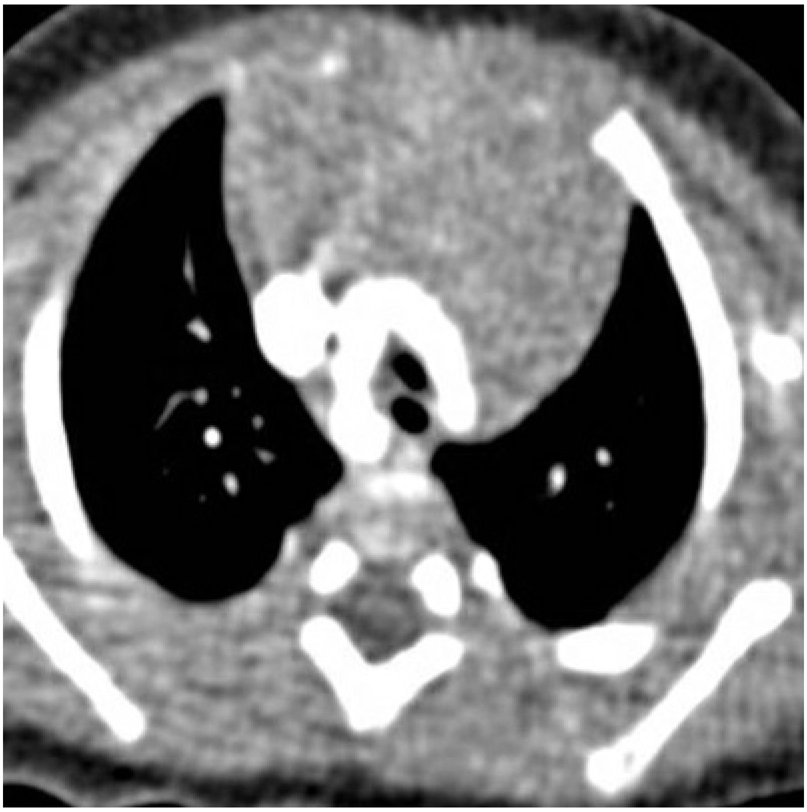

**FIG. 18.20** Double aortic arch demonstrated on computed tomography angiography, compressing the trachea.

2. *Anomalous innominate artery*—compresses the right anterior trachea
3. *Pulmonary artery sling*—compresses the lower trachea and the right and left main bronchi (Fig. 18.21)

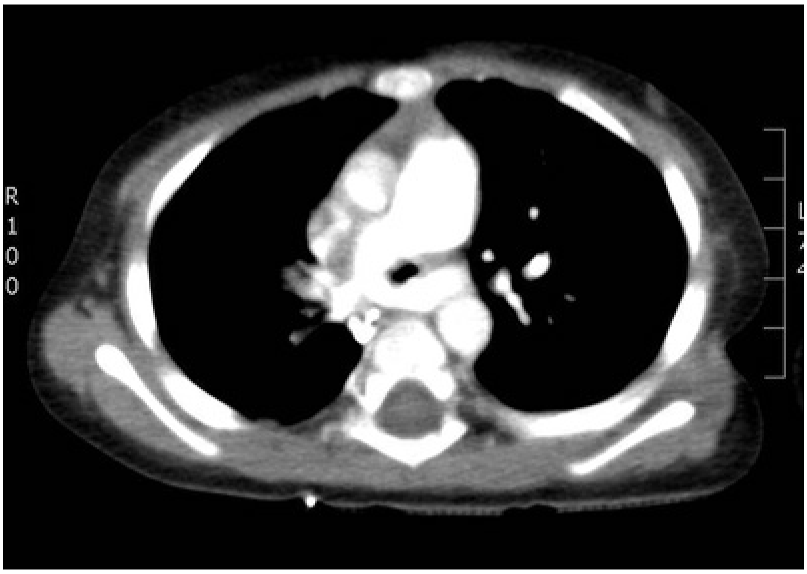

**FIG. 18.21** Computed tomography angiogram showing left pulmonary artery taking origin from the right pulmonary

artery, thus compressing the airway: a pulmonary artery sling.

Congenital tracheomalacia may be associated with bronchomalacia, particularly in more generalized cases. It also may be found with other tracheal abnormalities, such as TEF or laryngeal cleft. Although they may coexist, there is no connection with laryngomalacia.

The clinical manifestations of the condition are very variable, and it is often a diagnosis that can only be reliably made by endoscopy. There is likely to be stridor, which is usually expiratory as the obstruction is predominantly intrathoracic. There are usually recurrent acute episodes of stridor and dyspnea, during which the child may become cyanosed and moribund ("dying spells"). This may be precipitated by severe crying, coughing, or even feeding. The symptoms are usually apparent in the immediate neonatal period, but may deteriorate in the first and second year of life, in an almost stepwise manner.

Diagnosis is generally by endoscopy and subsequent tracheobronchography (Video 18.2▶). The pediatric airway is very elastic and may collapse during forceful inspiration and certainly during coughing fits. The membranous part of the trachea also tends to bulge forward, giving the impression of a narrow airway. During endoscopy, it is important that the child be adequately anesthetized to avoid coughing while there is still spontaneous respiration. There is no generally accepted definition of the degree of collapse that can be taken as abnormal, but it seems reasonable to suggest that more than 25% reduction of the lumen is a significant finding and that greater than 50% is likely to be symptomatic. As well as overdiagnosis, it is possible to miss the condition if the trachea is splinted by the bronchoscope or if there is excessive positive end-pressure applied by the anesthetist through the sidearm of the instrument. The procedure should involve a detailed laryngoscopy to screen for a laryngeal cleft, and active vocal cord movements should be confirmed, particularly if there has been tracheal surgery for a TEF or cardiovascular surgery for a vascular anomaly.

The diagnosis may be made (and later confirmed and quantified by bronchoscopy) with multiple detector CT scans; however, the radiation dose is significant, but can be reduced with variation of the expiratory phase of the investigation.[104]

## Treatment

Although the condition may progress in the first couple of years of life, it is generally self-limiting, and, if mild, it requires no active treatment. However, the patient's family should be taught cardiopulmonary resuscitation, particularly if the acute episodes are severe, and they can be provided with a facemask and ventilation bag. There may be associated recurrent respiratory infections, and training in home chest physiotherapy may need to be provided. In more severe cases, active treatment might be considered, though many of the choices have severe potential complications and should only be utilized in the face of extreme circumstances:

### Surgery for Abnormal Vasculature.

This may relieve the compression, though once the tracheal wall has become weakened from external pulsatile pressure, it may not immediately recover following the removal of the anomalous vessel.

### Aortopexy.

A suture through the adventitial lining of the aortic arch and the periosteum of the sternum is used to pull the arch forward. As the anterior tracheal wall is intimately connected to the aortic arch with fascial tissue, it is also towed forward, thus widening the tracheal lumen. There may be a failure of the suture, and there is a risk of damage to the aortic arch itself. This procedure can be performed via a thoracoscopic approach, which has the potential of reducing operative morbidity.[105,106]

### Tracheostomy.

This is very effective for short-segment tracheomalacia, but is unsatisfactory when the distal trachea is involved. The tube tip should pass through the segment to stent it; custom-made tubes can be manufactured to optimize the length. However, with a distal segment, the tube tip may pass into the right main bronchus on neck flexion and may not adequately stent the tracheomalacia segment on neck extension.

### Nasal or Tracheostomy Continuous Positive Airway Pressure.

A pneumatic splint of the segment can be achieved with continuous positive airway pressure (CPAP) via a tight-fitting facemask, or tracheostomy if the former is not tolerated, particularly with collapse at the carina (and in association with bronchomalacia).

### Internal Stents.

These have evolved significantly. Recent and bioabsorbable stents have fundamentally replaced the metal and siliconized plastic stents and avoid the inherent dangers of both. Complications include displacement, granulation tissue, and infection.

### External Stents.

These represent an evolving treatment modality with conventional materials such as Gortex tubes being replaced with 3D printed bioabsorbable materials. These are still experimental, but will likely represent the future for treatment of severe intractable malacia.

## Congenital Tracheal Stenosis (Complete Tracheal Rings)

In this very rare condition, there is a segment of the trachea, often distal, where the tracheal rings are truly complete. There may also be complete cartilage rings in the main bronchus (Fig. 18.22). It is often found in combination with other regional abnormalities, particularly cardiac, including pulmonary artery sling (see Fig. 18.21). In older children, large airway obstruction may be suspected from the appearances of the spirometric flow volume loop (Fig. 18.23). If the lumen of the trachea is small, this may not be compatible with life. Alternatively, the child may suffer immediate respiratory distress in the delivery room, which is not relieved by intubation or even tracheostomy. Extracorporeal oxygenation may be necessary to allow time to consider a surgical remedy.

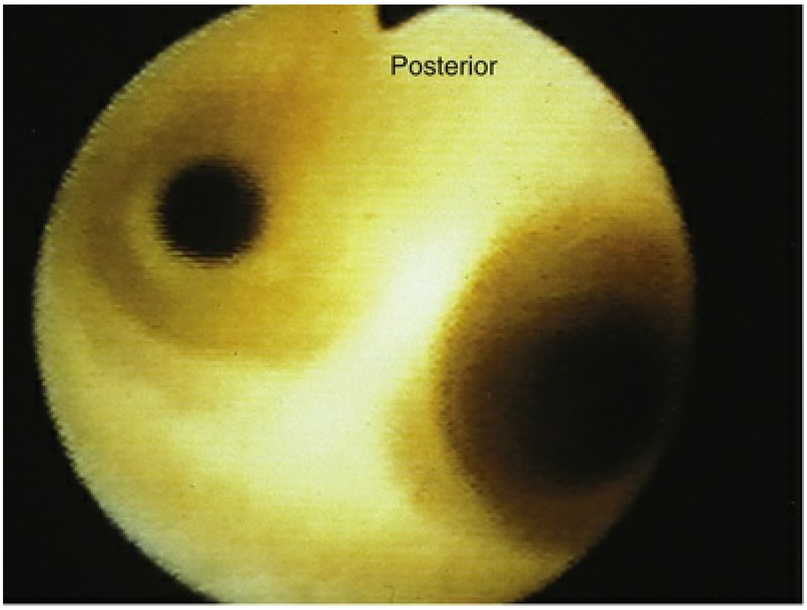

**FIG. 18.22** Bronchoscopic view of a single complete cartilage ring at the origin of the right main bronchus.

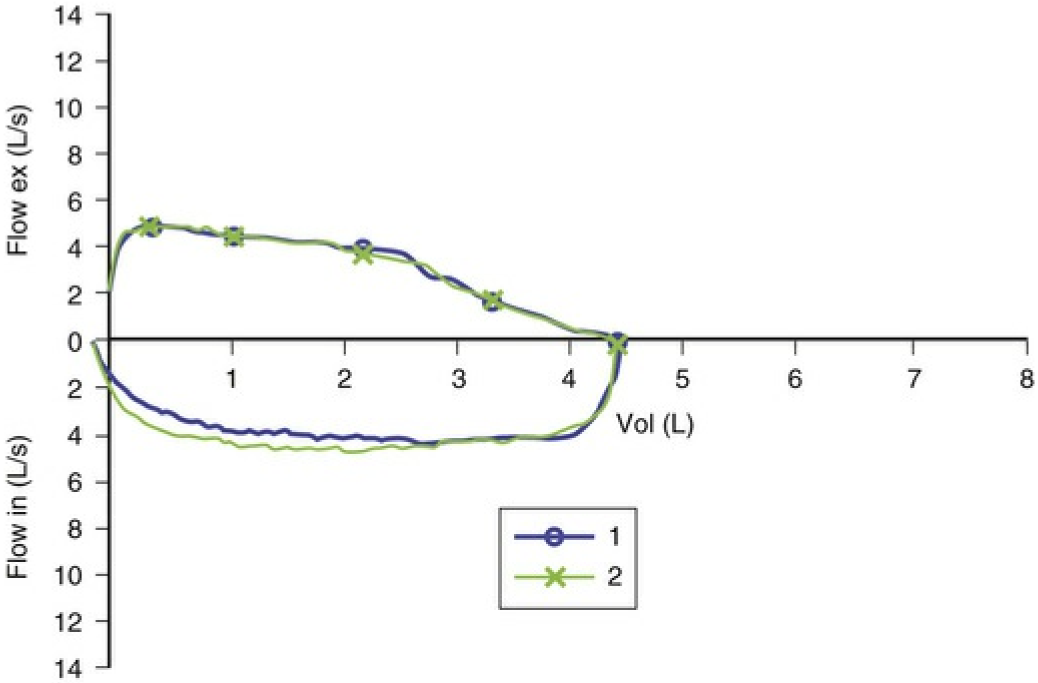

**FIG. 18.23** Typical appearance of the flow volume curve in fixed upper airway obstruction. There is marked abrupt attenuation of inspiratory and expiratory

flow, persisting until late near complete emptying, and then near complete filling of the lungs.

If the child is relatively stable, it may not be necessary to consider any form of tracheal surgery, and there is potential for airway growth with the child. However, it may become necessary as the child grows if exercise tolerance is severely limited. Where the child is failing to thrive, experiencing severe respiratory distress and recurrent infections, the gold standard treatment is surgical correction via slide tracheoplasty and concurrent correction of vascular anomaly. The largest series of these from GOSH analyzing 101 patients with a follow-up of up to 235 months, shows a mean actuarial survival of 88.4% assessment with validated quality of life studies in those patients showing no significant difference from the normal healthy population.[107]

Tissue-engineered tracheal transplantation represents an exciting avenue of future research and developing surgical techniques for this condition.[108] It still remains experimental and is only for compassionate use only.

# Specific Problems: Congenital Bronchial Abnormalities

## Congenital Bronchial Stenosis and Atresia

Congenital stricture of the bronchus occurs predominantly in a main stem or middle lobe bronchus and can produce acute and/or chronic pulmonary infection. Inflammatory scarring of the congenitally stenosed bronchus provides an ideal environment for distal suppuration, atelectasis, and bronchiectasis. Atresia is usually asymptomatic and detected incidentally on radiography, but may present with recurrent infection. The airway may be blocked by a simple membrane, or there may be a discontinuity. It often results in cystic degeneration of the lobe distal to the obstruction before birth, since fetal lung liquid continues to be secreted and cannot drain into the amniotic cavity. The distal airspace is often cystic and filled with mucus, and is typically in continuity with an area of distal hyperinflation caused by collateral ventilation. Bronchial atresia may be very difficult to distinguish from a CTM until the lesion is excised. Infection and scarring may ensue, with symptomatic presentation. Failure to identify the congenital nature of the problem may lead to a misdiagnosis of mucus plugging. Unlike the situation with absent bronchus, there is no focal opacity in CLHL (congenital lobar emphysema). The continuity of the cyst with the distal airways and the hyperinflation of the distal lung distinguish absent bronchus from bronchogenic cyst (the nomenclature of which is discussed later), but the two conditions are occasionally associated.

## Abnormal Bronchial Origin and Bronchial Branching

Bronchi can arise from the gastrointestinal tract. Bronchial diverticula also possibly represent abnormal bronchial branching. The right upper lobe bronchus can arise from the trachea, particularly in association with the tetralogy of Fallot. An accessory cardiac lobe bronchus may arise from the intermediate bronchus. A tracheal origin of one or more of the right upper lobe bronchi ("pig bronchus," Fig. 18.24) is usually of no clinical significance, but may be a cause of recurrent right upper lobe collapse in an intubated patient if the endotracheal tube (ETT) is low. The right lower lobe bronchus may also arise from the left bronchial tree, a "bridging bronchus." Lung segments may also cross over, with bronchial and arterial connections from the opposite side, usually from right to left. The crossover may simply be of vessels and bronchi, or include a tongue of parenchymal tissue, the "horseshoe" lung, where there is fusion of the lungs behind the heart.[109]

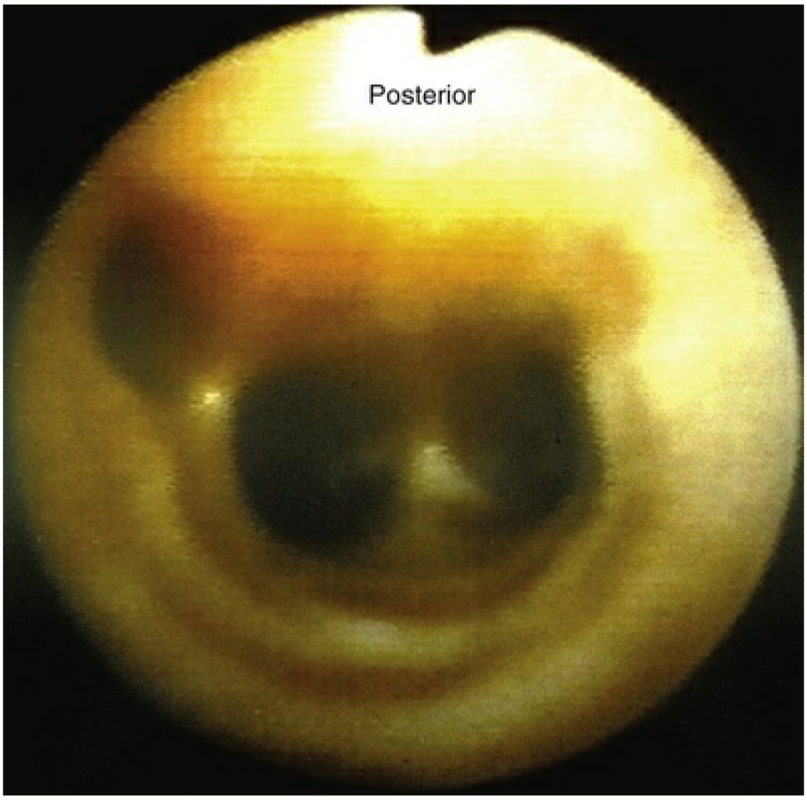

**FIG. 18.24** Bronchoscopic view of the right upper lobe bronchus taking off from the trachea (pig bronchus). This abnormality is usually not of any clinical significance.

## Disorders of Bronchial Laterality

Abnormal arrangements require consideration of what makes, for example, a right lung a right lung. It is not because it is in the right hemithorax. In clinical practice, the two most useful determinants of right lung morphology are the presence of three lobes, not two, and a very short main bronchus before the take-off of the upper lobe bronchus. A third criterion is the presence of an eparterial bronchus. Mirror-image arrangement must be distinguished from the superficially similar congenitally small (hypoplastic) right lung with right-sided heart (dextroposition) by determining bronchial morphology. This is important, because each has a different implication and requires different investigation. Mirror-image arrangement and other laterality disorders may be a feature of primary ciliary dyskinesia (discussed in Chapter 71), whereas a CSL must have its vascular supply delineated (see later).

The term "isomerism" is so entrenched that it is probably not feasible to replace it with, for example, bilateral right lung, which would be more logical. Nearly 80% of children with right isomerism (bilateral right lung) lack a spleen, leading to a risk of overwhelming pneumococcal sepsis. A similar proportion with left isomerism (bilateral left lung) have multiple small spleens. Ivemark's syndrome consists of right isomerism (bilateral right lung), asplenia, a midline liver, malrotation of the gut, and a variety of cardiac abnormalities including a common ventricle, totally anomalous pulmonary venous drainage, and bilateral superior caval veins and right atria. Left isomerism (bilateral left lung) is associated with multiple small spleens (polysplenia), a midline liver, malrotation of the gut, partially anomalous pulmonary venous drainage, and cardiac septal defects. Although nonfamilial, Ivemark syndrome is confined to males, whereas the other isomerism syndromes can affect either sex. A syndrome of left bronchial isomerism, normal atrial arrangement, and severe tracheobronchomalacia has been described,[110] extending the spectrum of left isomerism (bilateral left lung). Recently, the spectrum of primary ciliary dyskinesia has been broadened to include isomerism sequences (see Chapter 71).[111] Occasionally, a CSL may be so abnormal that its morphology can only be described as indeterminate. However, the contralateral lung morphology is usually obvious. Quite commonly, minor deviations from the normal bronchial branching pattern may be seen, which one study suggested may be associated with spontaneous pneumothorax.[112]

## Disorders of the Bronchial Wall

Abnormalities in bronchial wall caliber may result in all or part of the bronchial tree being too large or too small. These may present with recurrent infections, steroid-unresponsive wheeze, or stridor. Congenital tracheobronchomegaly (Mounier-Kuhn's syndrome) is characterized by tracheomalacia and bronchiectasis, with greatly dilated major airways.[113] There are saccular bulges between the cartilages. Bronchial clearance is impaired, resulting in recurrent respiratory infection. This syndrome, which may be autosomal recessive, generally presents between the ages of 30 and 50 years, and is more common in males. It is occasionally associated with Ehlers-Danlos syndrome, cutis laxa, or Kenny-Caffey syndrome.[114,115] True congenital bronchiectasis is much rarer than previously thought.

The lumen may be narrowed by complete cartilage rings (see Fig. 18.22). There may be an associated pulmonary artery sling (see Fig. 18.21). A short segment, situated relatively distally in the airway, may require no treatment. If ventilation is critically compromised, surgical excision or a Z-plasty may be indicated. Bronchoscopic balloon dilatation is increasingly being used. It is wise to ensure that the distal lung is normal before embarking on treatment; if the small airway is part of a generally maldeveloped segment, then enhancing ventilation may, in fact, only increase dead space ventilation.

Congenital bronchomalacia may be isolated, often with a good prognosis, at least in the short term, or associated with other congenital abnormalities including connective tissue disorders, and Larsen and Fryns syndrome. Williams and Campbell described a syndrome of diffuse bronchomalacia affecting the second to the seventh generations of bronchi.[116] Its occurrence in siblings, and the very early onset of symptoms, suggests a congenital etiology. Bronchomalacia also may be secondary to other congenital abnormalities, such as vascular rings. A rare cause of congenital tracheobronchomalacia is the presence of esophageal remnants in the wall of the trachea, which is generally associated with esophageal atresia and tracheoesophageal fistula. Fixed bronchial narrowing may be due to defects in the wall (e.g., complete cartilage rings) or extrinsic compression by an abnormal vessel or cyst.

## Presentations of Congenital Lung Disease in Childhood and Adult Life

Congenital lung disease may present later in childhood, or even in adult life. Respiratory distress as the sole presenting feature of congenital lung disease is rare after infancy. Many CTMs can present as an asymptomatic radiologic abnormality, including a focal solid or cystic mass, or hyperlucency. Unilateral CSL may also be a chance finding, and, if right-sided, may mimic mirror image arrangement. A cystic CTM enters the differential diagnosis of recurrent pneumonia in the same location, with failure of radiologic clearing between bouts or atelectasis due to large airway compression. More rarely, a cystic CTM may present as a lung abscess, atypical *Mycobacterial* infection,[117] focal bronchiectasis, pneumothorax, air embolism,[118] hemoptysis, or hemothorax, or even with malignant transformation, although it must be stressed that the latter is very rare; it is described in more detail below. Air embolism complicating air travel in a patient with a cystic CTM is rare, but may be fatal[119]; it is difficult to know what the best advice is for patients. The occurrence of any of this formidable but rare list of complications is extremely unusual in the first 2 years of life. Other conditions presenting with hemoptysis are any abnormalities characterized by abnormal systemic arterial supply and PAVM. The latter may also present with progressive cyanosis in a well person, which may lead to polycythemia, or with systemic abscess or embolism, including cerebral, due to bypass of the pulmonary vascular filter.

Another important presentation of congenital lung disease is as "steroid-resistant asthma." Large airway narrowing, such as tracheomalacia, vascular ring, or pulmonary artery sling, or complete cartilage rings enter the differential diagnosis; important physiologic clues come from the inspiratory and/or expiratory amputation of the flow volume curve, and the presence of a normal residual volume in the face of a greatly reduced $FEV_1$/FVC ratio (ratio of forced expiratory volume in one second to forced vital capacity).

Tracheoesophageal fistula and diaphragmatic hernia are considered the archetypal conditions presenting in the newborn period. However, both can present late. H-type tracheoesophageal fistula may present with recurrent bouts of coughing after drinking, or hemoptysis. Symptoms may have been present for more than 15 years.[120] Diagnosis is with a tube esophagram or bronchoscopy (Fig. 18.25). Diaphragmatic hernia usually presents with gastrointestinal symptoms later on, although abrupt presentation with respiratory distress has been described.[121] Whether some of these late-presenting hernias are truly congenital has been disputed.

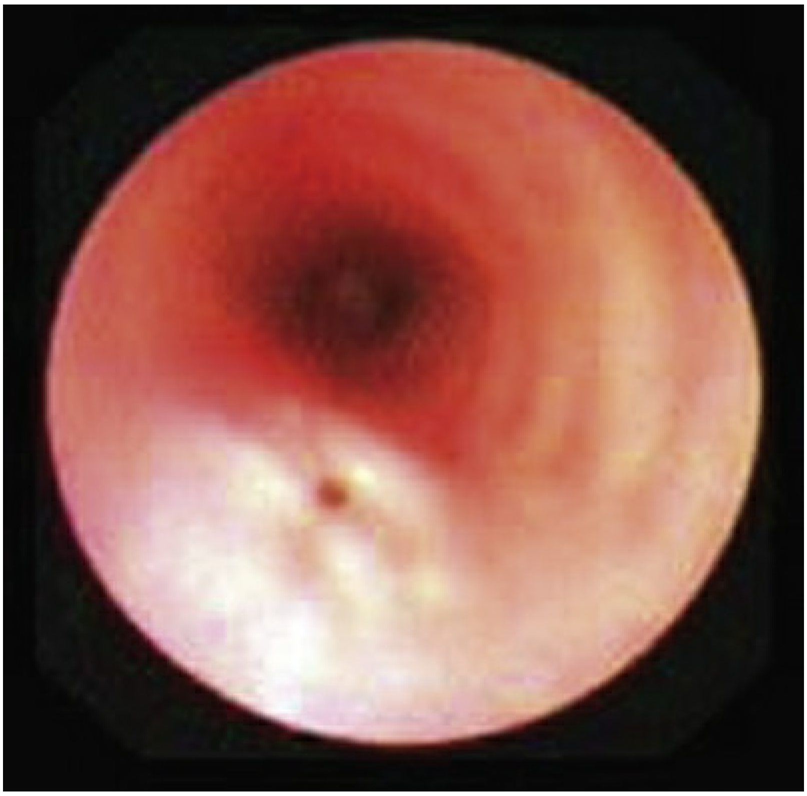

**FIG. 18.25** Bronchoscopic view of an H-type fistula *(arrow)* in a 6-year-old girl with recurrent respiratory infections from birth. This was missed by a tube esophagram.

It can be seen from the foregoing that congenital lung disease is not necessarily rare and esoteric, and important only up to the stage of early infancy, but that in many clinical scenarios it is worth asking, “Could there be a congenital thoracic disease present?” when considering the differential diagnosis. The next sections detail specific entities and their management.

# Specific Problems: Parenchymal Lesions

Numerous pathologic conditions present with cystic changes in the lung, with acquired lesions outnumbering those that are developmental in origin. It is usually only after surgical excision that accurate pathologic diagnoses can be made.

## Foregut (Bronchogenic) Cysts (Clinically,

## Cystic Congenital Thoracic Malformations)

Foregut cysts can be defined as closed epithelium-lined sacs developing abnormally in the thorax from the primitive developing upper gut and respiratory tract. When these structures differentiate toward airway and contain cartilage in the wall, they are termed bronchogenic cysts, while those developing toward the gut are termed enterogenous (or enteric) cysts, although they are most likely of common origin from abnormal division of the embryonic foregut.[122] Bronchogenic cysts are the most common cysts in infancy, although many do not present until old age. About 50% are situated in the mediastinum close to the carina, and less frequently adjacent to the esophagus and alongside the tracheobronchial tree. They may present as a palpable mass in the neck; more rarely, they are found within the lung parenchyma and exceptionally in sites, such as below the diaphragm, pericardium, presternal tissues, and skin.[123] Mediastinal cysts are more common in adults than in children. Foregut cysts are usually single, unilocular, and more common on the right. They may have a systemic blood supply. Symptoms often relate to compression of the airways or complications, such as hemorrhage or infection, which may be reflected in the macroscopic appearance when the wall is thickened by fibrous scarring and shows brown discoloration due to chronic bleeding (Fig. 18.26). Diagnosis is usually after surgical excision; in adults, endobronchial ultrasound and fine needle aspiration has been deployed, but iatrogenic infection may result.[124] Microscopic examination shows a cyst lined by respiratory-type epithelium, although there may be squamous metaplasia and even ulceration with a foreign body-type granulomatous reaction depending on secondary phenomena. The wall is often fibrous and inflamed, and it may contain seromucous glands and cartilage plates (Fig. 18.27). Adenocarcinoma and mucoepidermoid carcinoma arising in bronchogenic cysts have rarely been described.[125,126] In the absence of cartilage, such a cyst should be termed a simple foregut cyst.

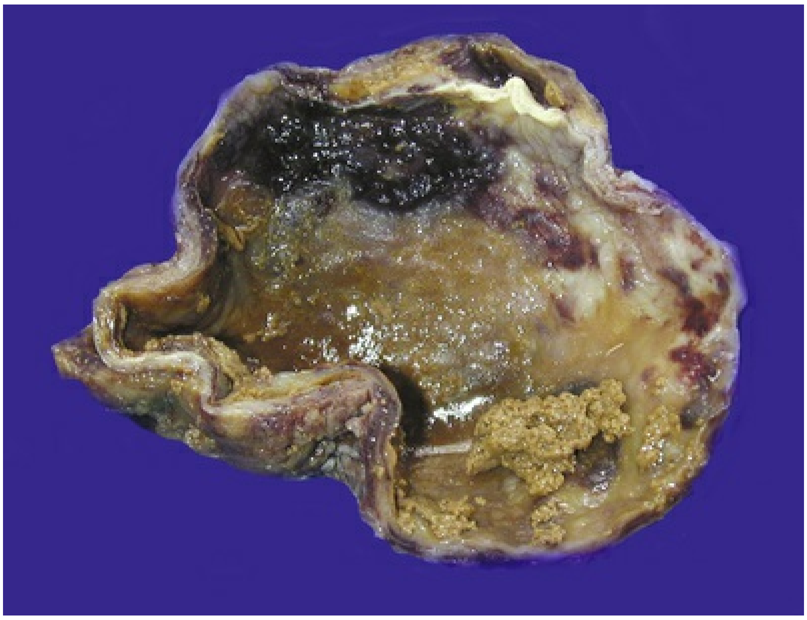

**FIG. 18.26** Mediastinal bronchogenic cyst. The inner surface of this unilocular cyst is partly hemorrhagic and partly covered by purulent debris, which is indicative of recurrent infection.

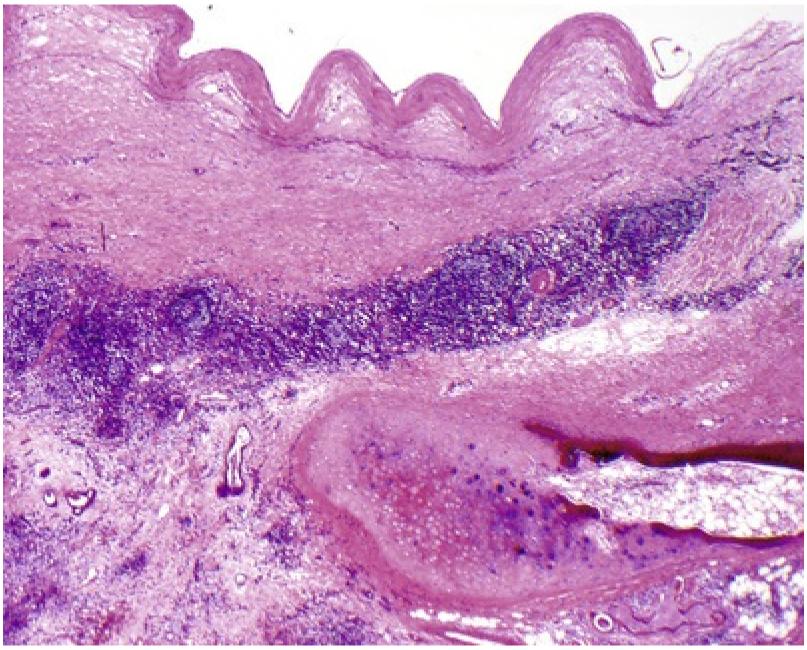

**FIG. 18.27** Mediastinal bronchogenic cyst. The lining of the cyst is mainly denuded, while the wall is chronically inflamed. Note the cartilage plate that indicates bronchogenic origin.

Enterogenous cysts are subdivided into esophageal and gastroenteric (duplication) cysts, the former being more common. Esophageal cysts are intramural and do not involve the mucosa. They are lined by either squamous or respiratory-type epithelium. Gastroenteric cysts, in contrast, are typically unconnected to the esophagus, but may be in close association with the thoracic vertebrae, often in the region of the sixth to the eighth. Symptoms are typically due to pressure, infection, or hemorrhage, and there may be symptoms in association with the vertebral anomalies. In infants, they are a common cause of a posterior mediastinal mass and are typically paravertebral in location. They may extend across the diaphragm. The cysts are often saccular and are lined by gastric or intestinal mucosa with a muscle layer akin to the muscularis propria. Gastric mucosa may cause symptoms due to ulceration. Malignant transformation is exceptionally rare but is reported in gastroenteric cysts.

## Congenital Pulmonary Airway Malformation

The term CPAM (clinically, cystic CTM) encompasses a spectrum of variably sized cysts with differing histology. The etiology of CTMs (whether CPAM, sequestration, or others) is little known. Rare familial cases have been described[127] and genetic studies have implicated Hoxb-5,[40] an epidermal growth factor receptor,[128] brain type fatty acid binding protein-7,[129] *fibroblast growth factor (FGF) 7, 9, and 10,*[130,131] alpha-2 integrin, and E-cadherin.[132] *FGF10* is a mesenchymal growth factor involved in branching morphogenesis in the embryonic lung. In a rat model, focal *FGF10* overexpression led to CTMs closely recapitulating those found in humans, the nature of which depended on the site (proximal vs. distal airway) and timing (pseudoglandular vs. canalicular phase) of overexpression.[131] This work suggests that the same gene mutation may cause different types of CTM depending on developmental factors, and it underscores the need to move to molecular-based classification of mutations. Indeed, it has been suggested that strong *FGF10, FGFR2b,* and *sonic hedgehog* signaling may differentiate CPAM from pleuropulmonary blastoma (PPB).[133] Other genes implicated in normal lung development, which, when knocked down or overexpressed in animal models, lead to congenital lung malformations are *FGF7, TGF-β1, TGF-β3* and *BMP4*.[134–137] Possible molecular mechanisms have recently been reviewed.[138,139]

CPAM encompasses a spectrum of variably sized cysts with differing histology. The relationship between different types and with other malformations is contentious, and their etiology is obscure. Originally classified as CCAM, the term *congenital pulmonary airway malformation* has become the favored terminology over the past decade as they are viewed as defects that relate to insults to the pulmonary airways during maturation, with the overarching more generic term *congenital thoracic malformation (CTM)* also used from a clinical perspective. Pathologically, five types (types 0–4) have been proposed by Stocker, the speculation being that they represent malformations relating to insults at different levels of the airways. In this classification system, type 0 (a condition formerly described as acinar dysplasia) is described as bronchial, type 1 as bronchial/bronchiolar, type 2 as bronchiolar, type 3 as bronchiolar/alveolar duct, and type 4 as peripheral.[2] Although lesions are not obviously distributed along the bronchial pathway, there is a high incidence of associated abnormalities of the bronchial tree on detailed analysis, and furthermore, vascularity and cellular composition in CPAMs corresponds to that seen in airways during gestation. This histologic classification is useful, because it permits identification of certain histologic patterns that rarely undergo malignant transformation in association with certain subtypes. However, this system has not been universally accepted, as discussed below, and many pathologists limit classification of CPAMs to types 1 and 2.[8]

## Type 0 Congenital Pulmonary Airway Malformation

Type 0 CPAM is also termed *acinar dysplasia*. The condition is rare,[140] is nearly always incompatible with life, and is typically associated with other abnormalities. The lungs are small and firm, and histology shows bronchial-type airways with cartilage, smooth muscle, and glands that are separated only by abundant mesenchymal tissue. Associations with genetic abnormalities, such as the T-box transcription factor *TBX4* gene,[141] the *fibroblast growth factor receptor 2 (FGR2)*,[142] and cases in siblings, have been reported.[143,144] A rare variant with some lung sparing and prolonged survival has been described,[144] although arguably this may not be a true type 0 CPAM.

## Type 1 Congenital Pulmonary Airway Malformation

Type 1 is the most common type of CPAM and has the best prognosis. This is because these malformations are usually localized and affect only part of one lobe.[145] Most present in the perinatal period or *in utero,* but rare cases can present later. CPAMs are usually multiloculated and range considerably in size, although the cysts in type 1 CPAMs are larger than 2 cm in diameter by definition (Fig. 18.28). There is no relationship between age and cyst size. Microscopically there is a sharp boundary between the lesion and the adjacent normal lung, but there is no capsule. The larger cystic spaces are lined by pseudostratified ciliated columnar epithelium, and the lung between the cysts may show bronchiolar overgrowth and underdeveloped alveolar parenchyma like type 2 CPAMs. Historically, mucous cell hyperplasia was described in 35%–50% of cases (Fig. 18.29) Arbitrarily, hyperplasia was defined as mucous cell proliferation confined to the cyst, while extensions of this process into the alveolar parenchyma with a lepidic growth pattern were classified as bronchioloalveolar carcinoma.[146] However, there is now greater understanding of the genetics of these lesions with *K-RAS* mutations being identified in the mucinous cells independent of location[147,148]; therefore, they are viewed as neoplastic. With changes in the classification of adenocarcinoma,[149] any areas of mucinous proliferation within a CPAM should be classified as a mucinous adenocarcinoma. If small (5 mm or less) and localized, this should be classified as a mucinous adenocarcinoma in situ. Nearly all cases are lepidic predominant; although they are rare, more invasive patterns and nonmucinous morphology have been described, with metastases.[150] Malignant transformation is rare in CPAMs,[151] although nonresolving areas of consolidation on imaging should raise concerns. There is a very good prognosis following complete resection, although recurrent disease has been described if incompletely resected, sometimes decades after the original resection of the cyst. CPAMs may also show evidence of superimposed infection when resected, including aspergilloma.

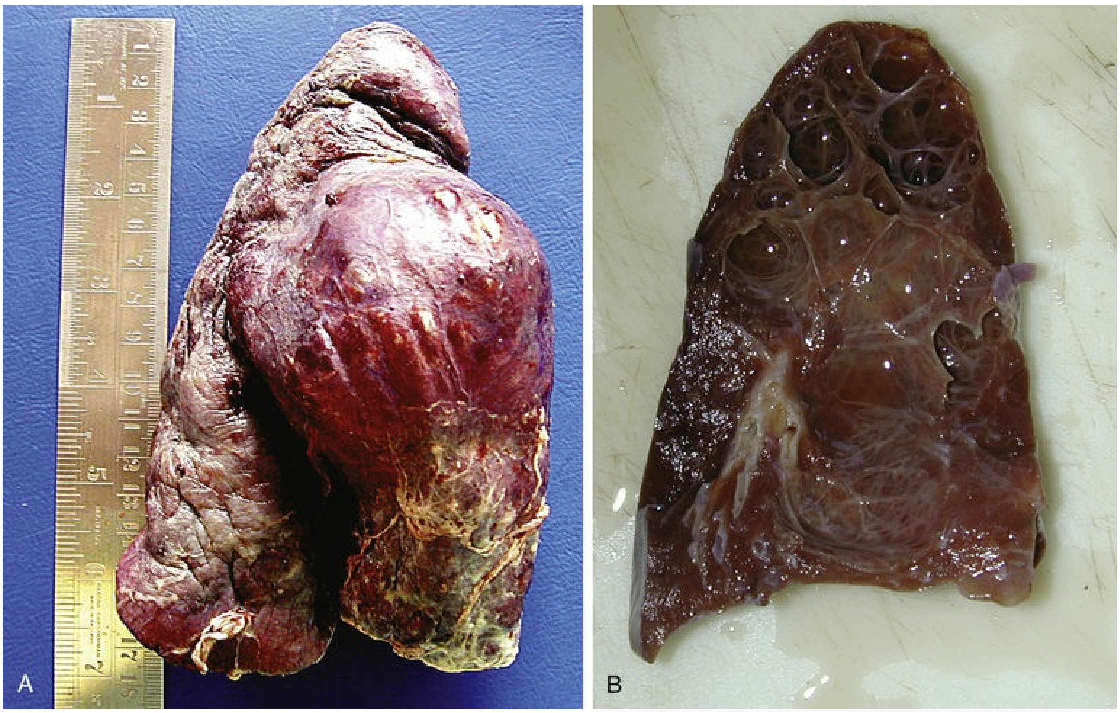

**FIG. 18.28** Type 1 congenital cystic adenomatoid malformation. (A) A cystic lesion bulges to fill most of the lower lobe. (B) The cut surface shows a multiloculated cyst replacing most of the parenchyma.

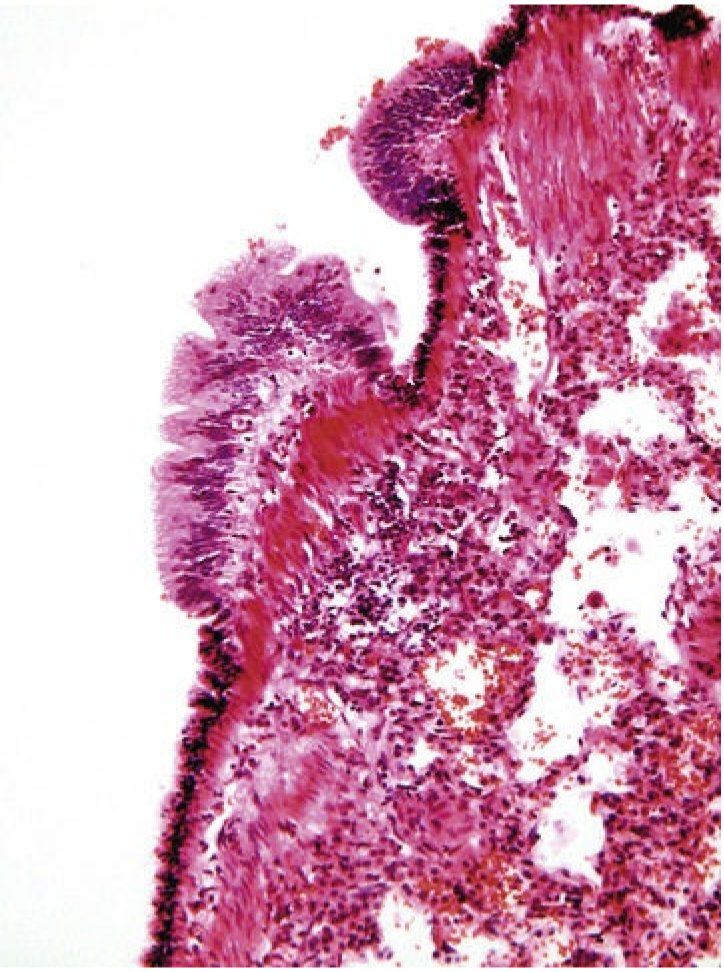

**FIG. 18.29** Type 1 congenital cystic adenomatoid malformation. The cyst lining is mainly of respiratory-type, although mucous cell hyperplasia is not infrequently seen.

## Type 2 Congenital Pulmonary Airway Malformation

This is the second most frequent type. They generally cause respiratory distress in the first month of life and may be associated with renal agenesis, cardiovascular defects, diaphragmatic hernia, and syringomyelia, which often have an additional adverse effect on the prognosis. Occasional cases present later in childhood with infection. Macroscopically, the lesions are spongelike, comprising multiple small cysts. Microscopically, the cystic airspaces relate to a relative overgrowth of dilated bronchiolar structures that are separated by alveolar tissue, which appears comparatively underdeveloped. Occasional examples contain striated muscle, although this has no clinical significance.

## Type 3 Congenital Pulmonary Airway Malformation

These are uncommon and occur almost exclusively in male infants. They typically involve and expand a whole lobe with the others being compressed. Therefore, these lesions may cause hypoplasia in the remaining pulmonary tissue. Macroscopically, they appear solid and not cystic. Microscopically, there is an excess of bronchiolar structures separated by airspaces that resemble late fetal lung. There is also a virtual absence of small, medium, and large pulmonary arteries within the lesion. Some regard this lesion as identical to pulmonary hyperplasia.[8]

## Type 4 Congenital Pulmonary Airway Malformation

These are also very rare and comprise peripheral thin-walled cysts that are often multiloculated. The cystic spaces are typically lined by alveolar type I or type II cells, with the intervening stroma being thin and comprising loose mesenchymal tissue (Fig. 18.30). Their etiology is obscure, and there is likely a spectrum of disease between these lesions and type 1 PPBs. Certainly, if the stroma of a suspected type 4 CPAM is even focally hypercellular, classification and management as type 1 PPB is recommended, and it has been proposed that such lesions lacking a blastematous component are better classified as regressed PPBs rather than Type 4 CPAM.[140,152,153]

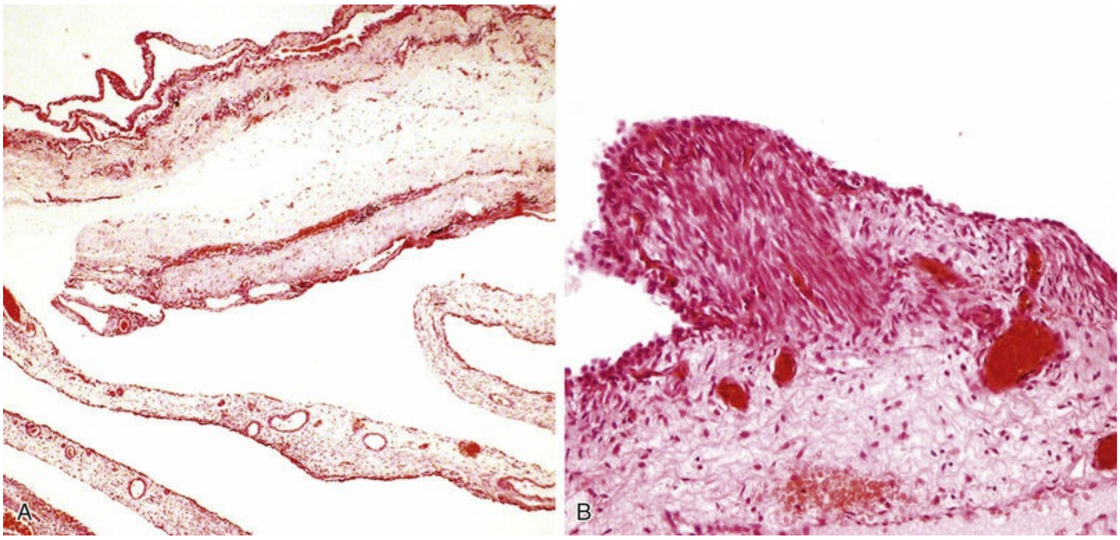

**FIG. 18.30** Type 4 congenital cystic adenomatoid malformation. (A) These cysts are typically lined by pneumocytes with loose and myxoid fibrous stroma

comprising the walls of variably sized thin-walled cysts. (B) Care needs to be taken to ensure that no blastematous elements are present, which would then indicate a diagnosis of pleuropulmonary blastoma.

### A Rare Congenital Pulmonary Airway Malformation Variant: Cartilage and the Lung

Cartilage may be a feature of a number of cystic lesions; large cartilage islands have been described in giant cystic pulmonary chondroid hamartoma[154–156] and chondroid cystic malformation,[157] which may be considered a variant of CPAM.[158–160] Recently, five patients with diffuse cartilage islands scattered throughout the lung parenchyma were described.[161] Presentation was with neonatal respiratory distress in four children and a chance finding in the fifth. The initial diagnosis was of an interstitial lung disease. CT scanning showed diffuse abnormalities, including patchy ground glass change, linear opacities, and localized hyperinflation. Lung biopsy showed scattered mature cartilage islands within the lung. The prognosis was good, despite the widespread abnormalities.

## Postnatal Treatment Decisions in Congenital Cystic Lung Disease

Decisions about the treatment of a CTM that is symptomatic, either because of its size, compression of nearby structures, or because it has developed a complication, such as infection, are straightforward. For many abnormalities, surgery is the best and definitive treatment. For all but the smallest, sickest infants, lobectomy is a safe and well-tolerated procedure, with most surgeons reporting few, if any, significant sequelae. Segmentectomy may even be able to be done in some cases, with the preservation of normal lung tissue.[162] In one retrospective review, 14/60 patients suffered complications of surgery, including one each of tension pneumothorax, near-exsanguination, and chest wall fibromatosis close to the resection.[163] There were no deaths, and no reports of malignancy at follow-up. Increasingly, thoracoscopic surgery is used with results comparable to thoracotomy.[164] Chest tube drainage time and length of stay may be shorter with thoracoscopic procedures.[165,166] Long-term postoperative morbidity is not uncommon, and careful follow-up of patients submitted to surgery is recommended.[167] Pneumonectomy certainly carries a significant morbidity and mortality in infancy, but can be lifesaving.[168] However, it has considerable long-term morbidity, in particular scoliosis, which may worsen dramatically during the pubertal growth spurt.

It should be remembered that children with complex malformations (e.g., unilateral CSL with abnormal vasculature) may be asymptomatic for long periods despite a formidable list of abnormalities. A conservative approach, perhaps occluding any aortopulmonary collaterals, may be adequate.

Once a previously asymptomatic cystic lesion has become infected, it is probably safe to assume that recurrent infections are inevitable, and the lesion should be excised (Fig. 18.31). If medical management has failed, then surgical removal is indicated, conserving as much normal lung as possible. If the lesion is discovered as a chance finding on a chest radiograph, it is likely to be excised to establish the diagnosis and exclude a malignancy.

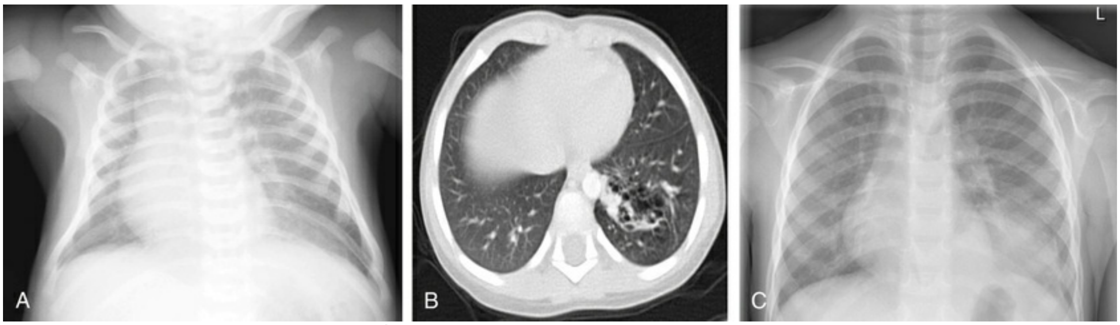

**FIG. 18.31** Infection in a congenital thoracic malformation. (A) Chest radiograph and (B) high-resolution computed tomography prior to the mass becoming infected. There is a multicystic mass with arterial supply from the aorta. (C) Chest radiograph when the child was febrile with respiratory distress. The mass has become infected, and was subsequently surgically removed.

No area is more controversial than that of the asymptomatic CTM discovered on antenatal ultrasound. A chest radiograph should be obtained postnatally in the asymptomatic child. However, this is only around 60% sensitive, so further imaging, usually HRCT, is advised to delineate the abnormality. If infant pulmonary function tests are performed, respiratory rates are found to be elevated and tidal volumes reduced, and lung compliance reduced,[169] but how this changes after surgery and whether they are useful in selecting babies who should be operated on is unclear. The question then arises, what to do next? Even surgeons, who almost by definition are interventionists, cannot agree,[170] and there are not enough natural history data to give sound advice to the parents. Trivial lesions will probably be left alone, but some would resect even tiny malformations, to try to reduce the risk of malignancy. However, there is no evidence that this policy works (below). A worrying recent study of 69 resection specimens of asymptomatic CTMs of various sorts revealed 18 (26%) had microscopic disease; $n = 16$ infection (7 microabscesses, 9 with inflammatory cell infiltration), and $n = 2$ PPB.[171] Reasons for operation on an asymptomatic CTM would include preventing nonmalignant complications; allowing optimal lung growth; and preventing malignant transformation. Unfortunately, there are important evidence gaps in all three areas.

Even if surgery has been decided upon, the optimal timing of surgery is unclear. The longer the lesion is left, the greater the risk of complications. A small, nonrandomized follow-up study assessing lung function using radionuclide imaging suggested results were optimal with surgery at less than a year of age,[172] but another study showed no difference in spirometry at follow-up whether lobectomy was performed before or after 2 years of age.[173] Clearly more data are needed.

## Prevention of (Nonmalignant) Complications

The main risk is probably infection. If the CTM is cystic, then it is likely (but unproven) that infection will eventually occur. The best information is from a large meta-analysis.[174] There were 41 series published between 1996 and 2008 describing 1070 patients, nearly 80% of whom had an antenatal diagnosis of CTM. A total of 505 reached infancy without surgery with only 16 (2.3%) becoming symptomatic. Complications were significantly less likely after elective surgery. Furthermore, previous pneumonia is a risk factor for the need to convert video-assisted thoracoscopic surgery to open thoracotomy.[175] The authors recommended surgery before 10 months of age, although the numbers who actually became symptomatic were too small to be dogmatic. Conversely, in a study from a center favoring conservative management, 72/74 fetuses with an antenatal diagnosis of CTM were liveborn; one required emergency lobectomy, and three others were electively operated on at parental request. For a median of 5 years, 65/68 infants remained asymptomatic.[176]

A more recent meta-analysis of studies comparing elective resection with expectant management identified only one prospective and eight retrospective studies. A total of 70 of 168 (42%) patients underwent elective surgery when asymptomatic, with a 10% surgical complication rate; 63 of 98 (64%) patients managed conservatively developed symptoms with a 32% complication rate.[177]

Clearly surgery will prevent nonmalignant complications of CTM, but if all CTMs were operated on, many unnecessary operations would be performed.

A final consideration is that removal of a CTM may reveal it was not as "asymptomatic" as was thought preoperatively. A single paper suggested that histiocytic inflammation may be a feature of some CTMs,[178] although no data about symptoms were given, and there was no evidence of chronic infection. However, anecdotally, the occasional infant who undergoes resection of an apparently asymptomatic malformation becomes much more alert and lively, and the family realizes that, in fact, all was not quite as well as was thought prior to resection of the CTM.

## Optimizing Lung Growth

It seems likely that operative removal of a large mass would allow the residual lung to expand. However, evidence in support of this is scant. Indeed, CLHL (congenital lobar emphysema) may cause considerable mediastinal shift in asymptomatic infants, but as the child gets older, the shift regresses and there is no evidence of interference with lung growth or function. Indeed, CLHL may be a chance finding in a completely asymptomatic adult.[179] Such information as is available on infant lung function tests in CTMs suggests that they are associated with an mildly decreased tidal volumes, an increased respiratory rate, and decreased lung compliance,[169] but follow-up studies are lacking. Hence we do not believe that optimizing lung growth is a credible indication for removal of an asymptomatic CTM.

## Prevention of Malignant Transformation

This is a vexed and difficult issue.[180] A few definite background statements can be made:

- Primary intrathoracic malignancy in childhood is very rare indeed, and for most (but not all) types of CTM, there is no evidence of an increased risk, and cytogenetic studies are reassuring.[181]
- There are several case reports and case series documenting the coexistence of a CTM and primary intrathoracic malignancy, mainly invasive mucinous adenocarcinomas associated with type 1 CPAMs.[174,182,183]
- Tumor markers are found in CTMs, and these may be associated with malignancy; these include Echinoderm microtubule-associated proteinlike 4 (EML4)-anaplastic lymphoma kinase (ALK) fusion-type oncoprotein,[184] MUC5AC, CK20, erythroblastic leukemia viral oncogene homologue 2 (HER2), and *K-Ras*.[185–187]
- Even complete removal of a CTM does not prevent development of a malignancy.[188,189]

The most informative study came from Canada, over the period from 1998 to 2008, in a population of around 5 million with 1,187,484 live births during the study period.[190] A total of 129 children were diagnosed with a CTM (CPAM)—the incidence being one in 12,000—and 74 underwent a resection. The reasons for resection were generally poorly documented. A total of 5 PPBs were diagnosed during this time period, giving an incidence of 1 in 250,000 live births. Three were initially diagnosed as a CPAM. Thus the incidence of PPB among apparently benign CTMs is 4%, and, worryingly, there was no clinical or radiological feature that distinguished benign from malignant. One of the two patients (both of whom were late-presenting) who had a PPB without a preexisting lung lesion, died.

Placing CPAM patients into high- and low-risk categories may be feasible with an algorithm incorporating radiological features and *DICER1* mutation analysis.[191] Radiological features suggestive of uncomplicated CPAM include antenatal detection and the presence of a systemic feeding vessel and hyperinflated lung. Features suggestive of PPB included bilateral or multisegment involvement. Although this is a large study (more than 100 patients in each group) this algorithm should be used with caution until prospectively validated in another cohort. CT features overlap between CPAM/sequestration and PPB.[192,193]

It has been suggested that some CTMs may be associated with the development of sarcomas, but these are most likely PPBs with a cystic component as part of the tumor. Indeed, it has been proposed that a type 4 CPAM is better classified as a regressed PPB.[153,194] Registry data suggest that those with bilateral CTMs, a family history of PPB, lung cysts or renal anomalies, or a close relative with a childhood malignancy—especially Wilms or medulloblastoma—are at particular risk.[153,181,195,196] Recently, attention has focused on DICER1, a cytoplasmic endoribonuclease that cleaves precursor molecules into microRNAs that modulate mRNA expression. DICER1 is very important developmentally, null mutations being embryo lethal in animals.[197] Registry data show a rate of 68%[195] in PPB. At least 40 heterozygous germline mutations in DICER1 have been described, and have been shown to be important in PPB,[198] as well as a spectrum of malignancies, including cystic nephroma and Wilms tumor, ovarian sex-cord-stromal tumors, multinodular goiter, embryonal rhabdomyosarcoma of the uterine cervix, pleomorphic sarcoma of the thigh, primitive neuroectodermal tumor, pulmonary sequestration, and juvenile intestinal polyps. However, even if the clinical picture and/or the presence of DICER1 mutations puts the child in a high-risk group and leads to excision of the CTM, there is no established protocol for postoperative follow-up and imaging. Although screening for DICER1 mutations should be considered in the families of a child with PPB before this is undertaken, skilled genetic counselling is advisable to determine what should be offered to those who screen positive.[199]

## Summary and Conclusions

The uncertainties as to what best to do must be shared honestly with the family. There is no one right answer in the asymptomatic child, and this should be acknowledged. Follow-up to obtain natural history data is recommended, whatever therapeutic decisions are made. Our own view is that asymptomatic congenital cystic disease merits surgery:

- There is about a 3% risk of complications, such as infection, bleeding, and air leak in childhood; whether the risk increases with age is not known.
- There is about a 4% risk of malignancy, which admittedly can be reduced but not eliminated by surgery.
- There is a very small and unquantifiable risk of complications of air travel, but these can be devastating.
- Taken together, the above risks outweigh those of elective surgery in skilled hands.

However, many would disagree, and until we have better means of assessing the risk of complications, the present unsatisfactory state of affairs will likely continue.

## Pulmonary Sequestration

The etiology of these lesions is not clear, and specifically, genetic studies have tended to lump sequestrations and CPAMs together (probably logically!). Given the difficulty of distinguishing sequestration from CPAM, other than by pathological examination, and with overlapping findings even then, many of the difficulties in planning treatment are common to both. The classical definition of sequestration is pulmonary tissue that is isolated from normal functioning lung and is nourished by systemic arteries, although the separation may be purely vascular. The intrapulmonary variant is contained within otherwise normal lung parenchyma. The less common extralobar sequestration is divorced from and accessory to the lung. Sequestrations may also connect to the esophagus or stomach, or contain pancreatic tissue; they may also show histologic features of adenomatoid malformations. These complicated lesions are perhaps best classified pathologically as complex "bronchopulmonary-foregut malformation," if the simpler term CTM is not to be used.

Their etiology is far from understood, with various proposed theories. Some workers have suggested that intralobar sequestration is acquired when a focus of infection or scarring acquires its blood supply from a systemic collateral, basing this on the relative sparsity of other malformations associated with this type of sequestration and its rarity in perinatal autopsies; in such cases, intact bronchial ventilation would be expected. Those who believe sequestration to be congenital generally propose that accessory lung buds are fundamental to both forms of pulmonary sequestration and liken them to intestinal duplications, with subsequent acquisition of a blood supply from the nearest and most convenient source, which happens to be systemic.

Intralobar sequestrations are usually found in the posterior basal segment of the left lower lobe and extralobar sequestrations beneath the left lower lobe. About 15% of extralobar sequestrations are abdominal. The intralobar sequestration is encircled by visceral pleura and has no pleural separation from the rest of the lobe. The remainder of the affected lobe and lung is normal, unless secondary changes, such as infection, have supervened. More than half the cases of intralobar sequestration are diagnosed after adolescence, and symptoms in neonates and infants are uncommon. Extralobar sequestration is generally detected in infancy because of associated malformations and it affects males four times more frequently than females. Though much rarer, intralobar sequestrations also may be associated with other malformations.

The largest series of sequestrations is a retrospective review of 2625 cases from China, over the period 1998–2008[200]; it appeared that all were diagnosed postnatally, and antenatal screening was uncommonly performed, if at all. They were more common in males (gender ratio 1.58 : 1), 13% were asymptomatic, and the rest presented with nonspecific symptoms, such as cough, fever, and chest pain. Intralobar sequestration was more common than extralobar (84% vs. 16%). Presentation with acute chest pain due to torsion of a sequestration has been described very rarely.[201] Extralobar sequestrations tended to be asymptomatic and diagnosed later. CT appearances were variable, and included a solid mass (49%), a cystic appearance (28.6%), a cavitating mass (11.6%), and appearances suggestive of pneumonia (8%), similar to other series.[202] Only three patients had bilateral lesions. The left lower lobe was the most common site, especially left (66.4%) and right (20.1%) posterior basal segments. Arterial blood supply was most commonly from the thoracic (76.6%) or abdominal (18.5%) aorta, more than 20% had at least two arteries supplying the abnormality. A celiac, splenic, or coronary artery source of arterial supply has been described. More than 90% were drained by the pulmonary venous system; some may drain into the hemi-azygous system or inferior caval vein. In nearly 60% of cases, the preoperative diagnosis was wrong. Calcification is rare in sequestrations, but may be seen in the arterial supply if there is premature atherosclerosis. In another series,[203] the mean age at presentation of 72 patients was 36.6 years. Presenting symptoms were nonspecific and more than 60% of all lesions were undiagnosed preoperatively, despite CT imaging. *Aspergillus fumigatus* and *Pseudomonas aeruginosa* were the most common organisms cultured from the resected specimens. *Mycobacterium tuberculosis* and *Nocardia* infection have been described in other series.[204–206] Changes typically associated with pulmonary hypertension (medial hypertrophy, intimal proliferation, plexogenic lesions) may be seen in many of these lesions.[207]

Treatment of sequestration may be by surgical excision (open or thoracoscopic) or embolization,[208] and both are very safe in experienced hands. Before surgery, as with all CTMs, the vascular supply should be carefully delineated by preoperative investigations (see later) and embolization of aortopulmonary collaterals at least considered. There is an increasing number of series of definitive treatment by embolization, in some cases very early in life.[209,210] The results are better for solid lesions; cystic components do not respond so well. Embolization has also been used to control massive hemoptysis.[211] Surgery is clearly the preferred option if the mass is infected or, particularly in an adult, malignancy is suspected. Embolization will abolish shunting and the risk of high-output cardiac failure, but will likely leave residual tissue. Whether this matters depends on the assessment of the (currently unquantifiable) risk of malignancy in a sequestration. There are case reports of sequestration being associated with elevated serum and intralesional tumor markers[212] and frank malignancy (adenocarcinoma[213] and primary sarcoma[214]). A benign carcinoid arising in a sequestration as a chance finding has also been described.[215]

Both types of sequestration have certain similar pathologic characteristics as well as clear-cut differences. In both types, the pulmonary tissue is largely cystic and contains disorganized, airless alveoli, bronchi, cartilage, respiratory epithelium, and a systemic artery. It is often secondarily infected, bronchiectatic, or atelectatic, and may show histology of a CPAM, particularly type 2 CPAM in extralobar variants.[216,217] The aberrant arteries may arise from the thoracic or abdominal aorta and, in the latter instance, may pierce the diaphragm and run through the pulmonary ligament before reaching the sequestration. The elastic vessel walls may become atherosclerotic, and the lumen varies considerably in size. In intralobar sequestrations, the systemic arteries are likely to be large, and the veins drain into the pulmonary system; while in extralobar variants, the systemic arteries are small and the venous drainage is likewise systemic through the azygos system. The pulmonary vessels may show features of hypertension, although this does not appear to be of clinical significance.[217]

## Long-Term Follow-Up of Cystic Congenital Thoracic Malformations

There are several issues to be considered, including the effects of previous treatment (usually lung resection) and the needs of the child with a malformation that is being managed conservatively.

In general, lobectomy is well tolerated. The effects of lung resection have been reviewed[218]; issues include the total amount of resection and the age at operation (and thus the possibility of new lung tissue formation). Human and animal data are difficult to interpret, but in general it is the extent, not the age of the patient at resection that is important. Whether, when, and what imaging should be performed is controversial. The risks of radiation, especially in young children, should be taken seriously. Hopefully, in the next few years, MRI will be practicable in unsedated children, which should allow better follow-up.

# Specific Problems: Overexpansion, Aplasia and Ectopia

## Overexpansion: Congenital Large Hyperlucent Lobe (Congenital Lobar Emphysema)

A rare condition, CLHL presents in 50% of cases in the neonatal period, otherwise it is in early infancy. Some cases are caused by easily identifiable partial obstruction, such as mucosal flaps or twisting of the lobe on its pedicle. However, in many cases, a deficiency of bronchial cartilage is thought to be the cause, leading to inappropriate collapse of the airway and the trapping of air. Histologically, the majority of cases show normal radial alveolar counts, but with no apparent maturation with age when compared to age-matched controls, suggesting a postpartum arrest of acinar development within affected lung tissue. A minority of cases, however, show true alveolar hyperplasia with increased radial alveolar counts, which is sometimes referred to as a polyalveolar lobe.[219] The condition affects the left upper (42%), right middle

(35%), right upper (21%), and lower lobes (2%). The affected lobe cannot deflate, but overdistends and displaces adjacent lobes, and subsequently the mediastinal structures. The emphysematous lobe may herniate into the contralateral hemithorax, usually through the anterior mediastinum. The condition may be diagnosed antenatally (see earlier), may present as respiratory distress (often with consequent failure to thrive in infancy), or may be a chance finding on a chest radiograph taken later in life.

## Presentation in Infancy

Clinical features of infantile lobar emphysema are those suggestive of a tension pneumothorax: hyperresonance of the affected hemithorax associated with diminished breath sounds and deviation of mediastinal structures to the contralateral side. Usually, the chest radiograph will demonstrate a hyperlucent lobe with features of compression and collapse of adjacent lung and depression of the ipsilateral diaphragm (Fig. 18.32). The mediastinum is deviated, and the contralateral lung may be collapsed. Occasionally, initial chest radiographs may demonstrate an opaque lung field. This then clears and the affected lung becomes overinflated and hyperlucent on the radiograph. Ventilation-perfusion (V/Q) scanning may demonstrate delayed uptake and clearance of isotope and reduced blood flow in the affected lobe. This investigation is particularly useful if it is unclear whether the problem is a pathologically distended lobe on one side or a congenitally small contralateral lung, with secondary physiologic overexpansion. Bronchoscopy may reveal causes of intrinsic obstruction and permit the removal of a foreign body or inspissated secretions. An echocardiogram is valuable in evaluating the heart and great vessels, while a contrast CT scan is useful in evaluating the anatomy of the emphysematous lobe (its size and relations), and whether it has herniated into the contralateral hemithorax.[220] It is useful in demonstrating the nature of adjacent lobes of the lung. This investigation is also useful in excluding contralateral pulmonary hypoplasia.

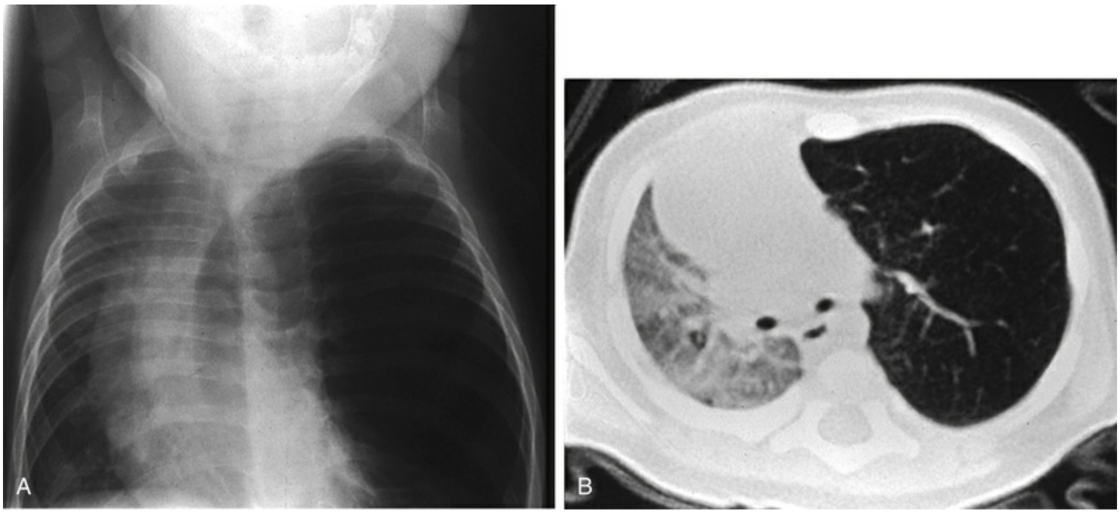

**FIG. 18.32** (A) Chest x-ray and (B) computed tomography scan of a congenital large hyperlucent lobe (congenital lobar emphysema).

## Differential Diagnosis

There are two broad groups of differential diagnoses. The first is any intrinsic or extrinsic cause of failure of airspace emptying. Intrinsic partial obstruction may result from inspissated mucus or aspirated material. Endobronchial granulomas due to ET suction may also result in obstruction of the airway.[221] Intrinsic obstruction due to bronchial atresia of the affected lobe is well recognized (Fig. 18.33). The affected parenchyma is ventilated collaterally, through the pores of Kohn, from adjacent normal lung. Extrinsic compression of bronchi due to congenital heart disease or anomalies of the great vessels usually presents as emphysematous changes of more gradual onset, often after the neonatal period. Less common causes of extrinsic compression include bronchogenic cysts. The other major differential diagnosis group is any cause of loss of lung volume on the contralateral side. These causes include absent lung, and lobar or lung collapse due to bronchial obstruction. Mediastinal shift with an opaque large lung, an occasional early finding in CLHL, should be distinguished from other causes of unilateral opacification and contralateral mediastinal shift in the neonate, such as chylothorax, CDH, or airless congenital CTM.

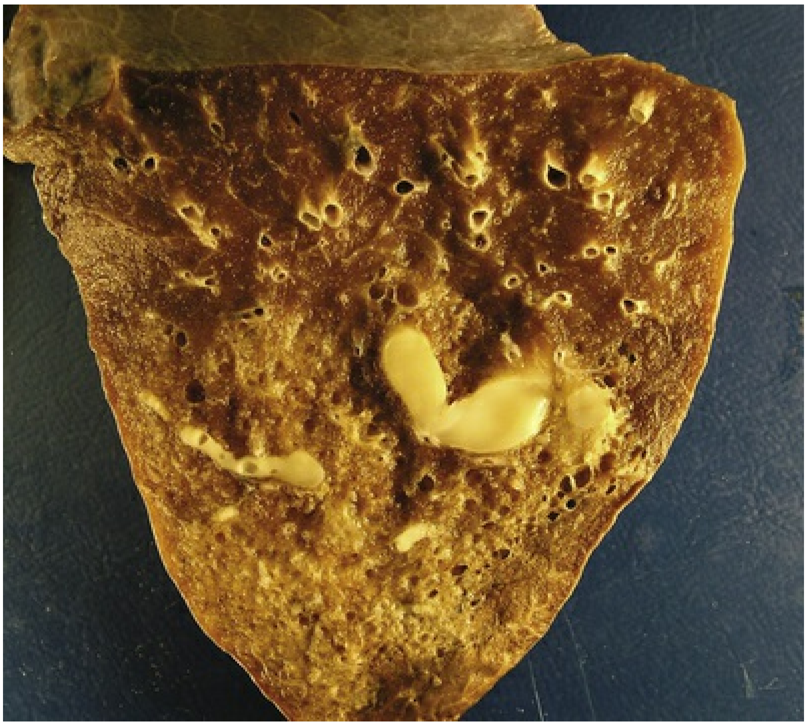

**FIG. 18.33** Bronchial atresia. The cut surface of the lung shows dilated airways plugged with mucus with surrounding microcystic changes. Dissection showed atresia at the origin of the apical segmental bronchus.

## Treatment

Those children who do not suffer respiratory compromise can be managed conservatively. Their outcome is comparable those children managed by resection of an emphysematous lobe (Fig. 18.34); the distended emphysematous lobe does not compromise the growth and development of the adjacent lung.[222] Lobectomy is indicated in the event of respiratory distress, which rarely, if ever, develops de novo beyond the newborn period. The actual surgical technique is as for any other lobectomy. Ventilation in this circumstance may be difficult. Low-pressure, high-frequency oscillation has been advocated to prevent barotrauma to the affected lobe and further respiratory compromise to the adjacent lung.

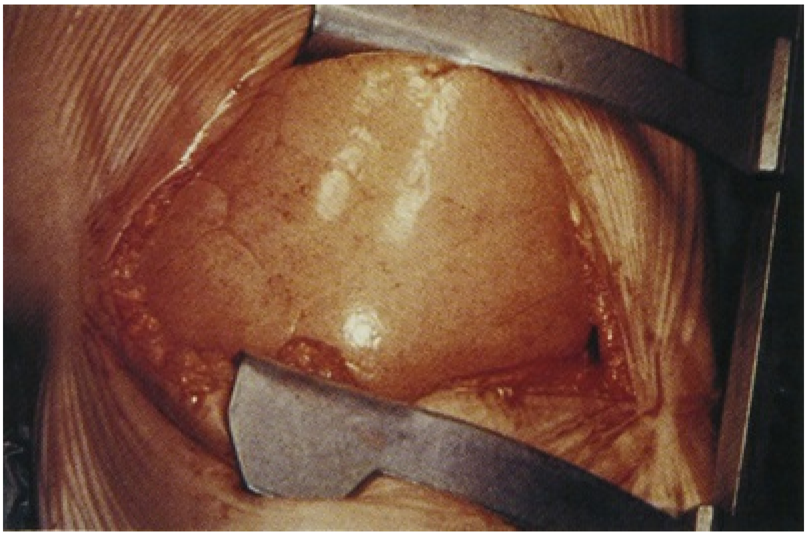

**FIG. 18.34** Surgery for congenital large hyperlucent lobe (congenital lobar emphysema). The hyperexpanded lobe protrudes out of the thoracotomy incision.

## Pulmonary Agenesis, Aplasia (Absent Lung), and Hypoplasia (Small Lung)

Bilateral pulmonary agenesis is a rare malformation that may occur in anencephaly. Unilateral pulmonary agenesis is slightly more common, with the absence of the carina, and with the trachea running directly into a single bronchus. Pulmonary agenesis may be divided into three types (Box 18.4).

### Box 18.4

### Classification of Pulmonary Agenesis

Agenesis, with no lung parenchyma, bronchus, or vascular supply
Aplasia, absent lung tissue and pulmonary artery, rudimentary bronchus
Hypoplasia, rudimentary lung, and bronchial tree

Pathologically, the sole lung is larger than normal in pulmonary agenesis, and this enlargement is true hypertrophy and not emphysema. Prevalence has been estimated at 0.34 per 100,000 live births.[223] Associated ipsilateral and other congenital abnormalities (cardiac, gastrointestinal, skeletal, vascular, genitourinary, and craniofacial are common.[224,225] Velocardiofacial syndromes, di George and Goldenhar syndromes, and VACTERL association have all been described in this setting. Associated pulmonary abnormalities are contralateral hypoplasia, complete tracheal rings, and tracheomalacia. There may be an association with duplications of chromosome 2.[226] The mortality of right-sided agenesis is twice that of left-sided agenesis; this is probably a result of more severe mediastinal and cardiac displacement. However, prolonged survival has been reported.[227] Pulmonary aplasia, the most common variant, consists of a carina and main-stem bronchial stump with unilateral absence of the distal lung. In this situation, secretions can pool in the stump, become infected, and possibly spill over to infect the sole lung. Lobar agenesis and aplasia are rarer than complete absence of one lung and usually affect the right upper and middle lobes together. Pulmonary hypoplasia (CSLs) consists of incompletely developed lung parenchyma connected to bronchi that may also be underdeveloped depending on when the presumed causal insult took effect in embryogenesis. There are a large number of causes of CSLs (Tables 18.9 and 18.10). The alveoli are reduced in number or size (numbers are assessed by counting alveolar wall intercepts on a line from the terminal bronchiole to the interlobular septum). However, hypoplasia is perhaps best considered to be present in term babies when the lung-to-body weight ratio is less than 0.012. There is a high incidence (around 50%) of associated diaphragmatic, cardiac, gastrointestinal, genitourinary, and skeletal malformations, as well as frequent variations in the bronchopulmonary vasculature. Correction of any underlying abnormality, if feasible, either postnatally or antenatally, may permit the growth of alveoli. However, airway branching is complete by 16 weeks, so airways will not branch after a causal abnormality has been corrected; since the airway pattern is abnormal, alveolar numbers are never likely to be normal.

---

**Table 18.9**

### Causes of Bilateral Congenital Small Lungs

| System Fault | Example |
|---|---|
| Lack of space | Abnormal thoracic, abdominal, or amniotic cavity contents |
| Abnormal vascular supply | Pulmonary valve or artery stenosis<br>Tetralogy of Fallot |
| Neuromuscular disease | CNS, anterior horn cell, peripheral nerve or muscle disease (particularly severe spinal muscular atrophy and myotonic dystrophy inherited from mother) reducing fetal breathing movements |

*CNS*, Central nervous system.

## Table 18.10

### Congenital Small Lungs Due to Extrapulmonary Mechanical Factors

| | |
|---|---|
| Abnormal thoracic contents | Diaphragmatic hernia<br>Pleural effusion<br>Large CTM |
| Thoracic compression from below | Abdominal tumors<br>Ascites |
| Thoracic compression from the sides | Amniotic bands<br>Oligohydramnios (any cause)<br>Asphyxiating dystrophy/scoliosis or other chest wall deformity |

*CTM*, Congenital thoracic malformation.

# Ectopia

Ectopia is growth of normal tissue in the incorrect anatomic position and, in relation to the lung, comprises either nonpulmonary tissues being present in the lung or lung tissue outside the thoracic cavity.[228,229] In relation to extrapulmonary tissues, ectopic glial tissue is well recognized within the lung, with nodules of glial tissue being implanted in anencephalics or due to embolization in relation to intrauterine trauma. Adrenocortical tissue, thyroid, liver, and skeletal muscle have also been described in the lung, and pancreatic tissue has been found in intralobar sequestrations. Ectopic lung tissue may be found in the neck, chest wall, and even in the abdomen, although some ectopias represent extralobar sequestrations. Alternative terms for this occurrence include congenital pneumatocele and congenital pulmonary hernia, although they are best regarded as true ectopias. Entire kidneys may also be intrathoracic in location.

# Specific Problems: Abnormal Connections Between the Bronchial Tree and Other Structures

## Tracheoesophageal Fistula and Esophageal Atresia

### Etiology

The environmental, chromosomal, and genetic abnormalities implicated in these conditions have recently been reviewed.[230–233] Deletions in the glutathione S-transferase gene have been implicated in isolated esophageal atresia.[234] Genetic factors implicated in esophageal atresia as part of a syndrome include *CHD7* in familial CHARGE syndrome,[235] *FOXF1* and the 16q24.1 FOX transcription factor gene cluster,[236] and polyalanine expansion in the *ZIC3* gene[237] (both VACTERL), and a 5.9 Mb microdeletion in chromosome band 17q22-q23.2 associated with TEF and conductive hearing loss.[238]

#### Pathology.

If there is incomplete mesodermal separation of the primitive foregut, then a fistula may develop between the esophagus and the trachea (see Fig. 18.25). Most commonly, they are associated with esophageal atresia, with about 85% of such cases being associated with a fistula. Typically, the proximal part of the esophagus ends in a blind sac, and the distal part takes origin from the lower part of the trachea. The upper blind pouch is large and substantial, and usually ends about 8 cm from the superior alveolar ridge in the region of the azygos vein. Conversely, the lower esophageal segment is small and originates from the region of the distal posterior membranous trachea, carina, or right main stem bronchus.

Instances of communication between the trachea and the esophagus with an otherwise normal esophagus occur in about 3% of tracheoesophageal fistulas (Fig. 18.35). Although symptoms from this congenital abnormality are fairly severe, the diagnosis is often delayed, with considerable respiratory morbidity due to aspiration and infection. The tracheoesophageal connection is almost always small, and the majority are found in the neck, from below the larynx to the thoracic inlet. Occasionally, a bronchus may communicate with the esophagus.

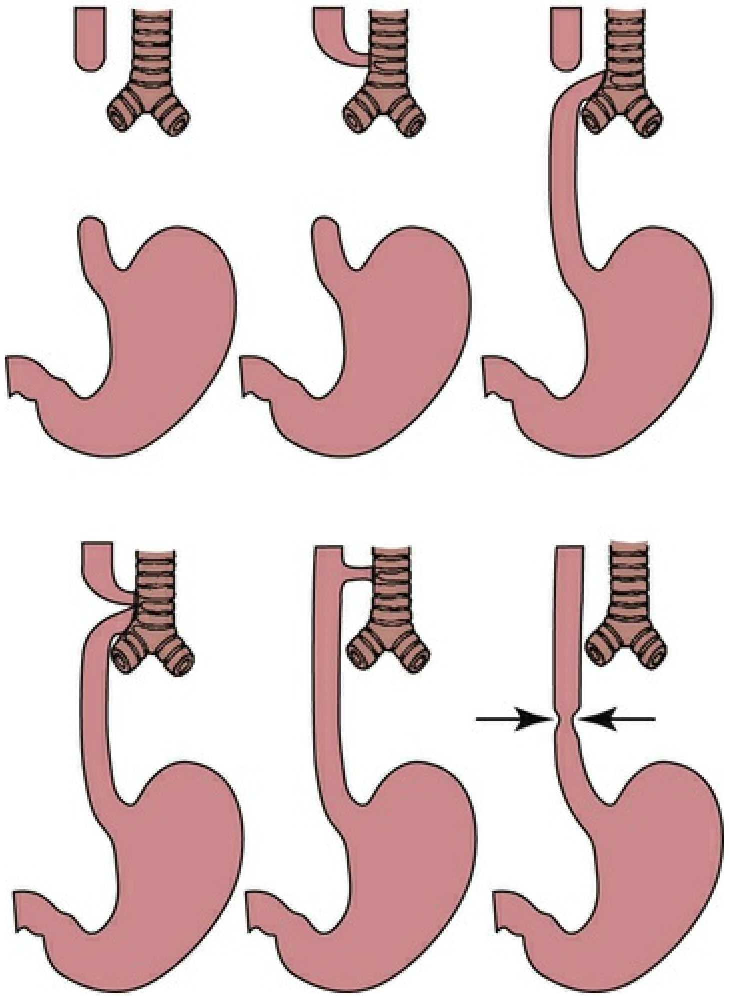

**FIG. 18.35** Types of tracheo-esophageal fistulae.

## Associations

Tracheoesophageal fistula is more common in first and twin pregnancies of mothers of increasing age. About two-thirds have an associated abnormality.[239] Of the live births, 20% have birth weights below the fifth centile. More than 50% of infants with esophageal atresia have associated anomalies. These are most common in pure esophageal atresia without fistula and least common in H-type fistula. The acronym VATER initially described vertebral, anal, tracheoesophageal, radial, and renal anomalies. This was then modified to VACTERL to include cardiac and limb problems. Infants with this association have a high mortality rate. Almost 80% have cardiac anomalies, these being the principal cause of death. Esophageal disease is also part of the CHARGE syndrome (coloboma, heart disease, choanal atresia, retarded growth, genital hypoplasia, and ear [deafness] abnormalities), which carries a high mortality. Chromosomal abnormalities are reported in 6% of cases, in trisomy 13, 18, and 21 in particular.[240] Other associations include Potter syndrome (bilateral renal agenesis), Pierre Robin, polysplenia, and DiGeorge sequences. The incidence of cardiac anomalies has been reported to be between 30% and 50% in various series. There is also a significant incidence (47%) of tracheobronchial anomalies[241] ranging from tracheomalacia, abnormal nonciliated epithelium, lung agenesis, and hypoplasia or ectopic bronchi, to glossoptosis and airway obstruction. Pharyngeal function and aspiration on deglutition is common. The incidence of vertebral and skeletal anomalies, ranging from sacral agenesis, hemivertebrae, and rib and radial anomalies is 20%–50% overall. Cases with associated cleft lip[242] and duodenal atresia are higher risk.

## Presentation

Maternal polyhydramnios has been reported in 85% of cases with pure esophageal atresia and 32% of those associated with tracheoesophageal fistula. Diagnosis by antenatal ultrasound is unreliable, with up to 50% false positives.[243] At birth, the baby is commonly frothing, choking, and suffering cyanotic episodes despite oral suction. If the condition is suspected, the initial examination should be carefully performed to identify any associated anomalies. The effect of birth weight and associated anomalies on survival is shown (Tables 18.11 and 18.12). An attempt should be made to pass an orogastric tube. Acid fluid may be aspirated from the tube if gastric contents reflux into the upper pouch across the fistula. A plain radiograph will demonstrate the tube coiled in the upper pouch and may identify pulmonary abnormalities, such as consolidation of the right upper lobe due to aspiration, plethoric lung fields due to cardiac anomalies, and vertebral and rib anomalies. The radiograph will reveal the presence or absence of gas in the stomach, indicating the presence or absence of a tracheoesophageal fistula. The intestinal gas pattern should be carefully examined on the abdominal radiograph to try to exclude distal intestinal atresia. An echocardiogram is useful to identify intracardiac structural anomalies and the possibility of a right-sided aortic arch.

### Table 18.11

### Waterson Classification of Esophageal Atresia, With Survival Figures

| Group | Classification | Survival |
|---|---|---|
| A | Birthweight >2500 g, otherwise well | 100% |
| B | Birthweight 2000–2500 g, otherwise well | 85% |
| | Birthweight >2500 g, moderate anomalies | |
| | Noncardiac anomalies including patent ductus arteriosus | |
| | Ventricular septal defect and atrial septal defect | |
| C | Birthweight <2000 g, severe cardiac anomalies | 65% |

### Table 18.12

### Spitz Classification of Esophageal Atresia, With Survival Figures

| Group | Classification | Survival |
|---|---|---|
| I | Birthweight >1500 g without congenital heart disease | 97% |
| II | Birthweight <1500 g or major congenital heart disease | 59% |
| III | Birthweight <1500 g and major congenital heart disease | 22% |

## Preoperative Care

The preoperative care for this condition should start from the moment it is suspected. Continuous suction of the oropharynx is important to reduce the risk of aspiration and thus protect the airway. A sump sucker, such as a Replogle tube, is useful, since it permits continuous suction and protects the esophageal mucosa from direct suction-related trauma.[243] Cyanotic episodes have been reported with the use of this form of suction of the upper pouch, and this is thought to be due to excessive negative pressure causing ineffective inspiration. The infant should be nursed prone. If pulmonary consolidation is identified, then physiotherapy and postural drainage should be employed.

## Surgery

The outcomes of either thoracoscopy or open thoracotomy have a similar complication rate.[244] A right thoractomy[245] with an extrapleural approach and end-to-end single-layer anastomosis and division of fistula remains the most common technique for the majority of children presenting with esophageal atresia and tracheoesophageal fistula. Routinely, the infant is fed by a transanastomotic tube. The use of intercostal drains and postoperative contrast studies varies between institutions and cases.[245] A variety of approaches have been proposed for those cases of esophageal atresia with a large distal fistula presenting with respiratory compromise due to gastric distention: ET intubation beyond the fistula orifice, Fogarty balloon occlusion of the fistula, and formation of gastrostomy. More recently, urgent thoracotomy and fistula ligation with primary or subsequent repair of the atresia has gained wider acceptance. Several preoperative and perioperative techniques have been proposed for cases wherein the distance between the proximal and distal segments is wide. The absolute length of the gap is not as relevant as its relation to the size and strength of the wall of the esophageal segments. Per pouch bougienage either preoperatively or perioperatively to shorten the gap has been widely described and more recently modified.[246] Perioperative techniques to facilitate primary anastomosis include the use of circular, transverse, or spiral myotomies of the upper pouch. More recently, alternative techniques have been proposed to repair long-gap esophageal atresia.[247] One alternative approach, described by Scharli,[248] is to mobilize the gastric cardia into the chest by thoracoabdominal approach, permitting division of the left gastric artery; favorable long-term results have been reported.[249] The primary thoracoscopic repair of esophageal atresia and tracheoesophageal fistula is well described. The possible advantages of this approach are being assessed.[250–252] Failing these techniques, the only option may be esophageal replacement by colonic, ileocolic, or gastric interposition. Each technique is associated with vagotomy, and requires a gastric drainage procedure. Proponents of each approach have described good results. More recently, gastric transposition has become a well-established substitute for esophageal replacement.[253] What is clear is that the advantages or otherwise of this plethora of surgical techniques will only be determined if careful follow-up studies are undertaken.

### Postoperative Course

Even after completely successful surgery, tracheomalacia is common, and the well-known brassy “tracheoesophageal fistula cough” (TEF cough) is a feature. Recurrent aspiration leading to bronchitis and bronchopneumonia is frequent. A missed diagnosis of laryngeal cleft should always be considered (see earlier). Occasionally, tracheomalacia may be so severe as to be life threatening, but generally the cough sounds more impressive than the consequences. Up to 17% of patients may require fundoplication for postoperative gastroesophageal reflux, and 25% have dysphagia at 2 years.[239] The early mortality associated with this condition is often related to the associated malformations, but the long-term outcome is good.[254,255]

## Other Abnormal Connections

Rare cases of direct communication between the bronchial tree and congenital cysts have been described. Congenital bronchobiliary fistula as part of upper gastrointestinal tract duplication is a source of bile in respiratory secretions. Rarely, a CTM may connect with the stomach and be associated with abdominal visceral malrotation. Conversely, the esophagus may give rise to the whole or part of a lung.[256]

# Specific Problems: Congenital Disease of the Pulmonary Arterial Tree

When surgery is contemplated for any CTM, it is important that any abnormal vasculature is identified in advance. Inadvertent severing of anomalous systemic arteries has led to fatal hemorrhage, whereas ligation of anomalous veins from adjacent nonsequestered lung has led to infarction of normal tissue. The pulmonary and systemic arterial trees must be considered separately. Systemic arterial abnormalities of the great vessels of the mediastinum can be separated into those of the bronchial circulation (normally 1%–2% of the left ventricular output) and other pathologic collaterals. The pulmonary capillary bed may be bypassed, leading to direct arteriovenous communication, or absent, resulting in minimal pulmonary arteriovenous connections.

## Disorders of Pulmonary Artery Arrangement

Pulmonary arterial and venous arrangement generally mirrors bronchial arrangement. Exceptions to this rule include congenital origin of the left pulmonary artery from the right (pulmonary artery sling) (Fig. 18.36). Presentation is the same as with any vascular ring (see earlier). In this condition, the left pulmonary artery has to traverse the mediastinum from right to left, compressing the trachea as it does so. There also may be a crossover arterial segment, with the right upper lobe supplied by a branch from the left pulmonary artery, so preoperative pulmonary angiography is essential. Surgical repair of a sling with a crossover may result in infarction of the right upper lobe if the abnormal vessel has not been discovered. Another association is complete cartilage rings (above), and the infant should be evaluated for this anomaly, probably before undergoing surgery. Isolated crossover pulmonary artery branches in the absence of bronchial crossover are occasionally seen. They cross the mediastinum to supply lung segments, which often are abnormal in other ways.

## Absent or Small Pulmonary Artery

Either lung may be affected by unilateral absence of a pulmonary artery (Video 18.3▶), and the defect may be isolated or associated with other cardiovascular anomalies, typically tetralogy of Fallot with an absent left pulmonary artery, and patent ductus arteriosus with an absent right pulmonary artery. There is an association with absent pulmonary valve syndrome. Symptoms may not arise until adult life, when they are generally due to pulmonary infection or hemorrhage. When there is only a short section absent, patients may be amenable to surgical correction, but usually the pulmonary vasculature is absent in much of the lung; histologic examination reveals hypertrophied bronchial arteries and often areas of dense fibrous scarring (Fig. 18.37). Normal pulmonary blood flow *in utero* and in the early postnatal period is needed for normal lung development. Before birth, less than 5% of the cardiac output reaches distal to the arterial duct, so it may seem surprising that interference with this small flow leads to underdevelopment of the alveolar bed and its vasculature, but there is considerable experimental evidence and clinical observation to confirm that this is so. Congenitally small unilateral pulmonary artery is usually seen in association with an ipsilateral small lung. However, it is unclear whether the primary abnormality is related to blood flow or whether both the small lung and the abnormal blood supply are due to an unknown primary event.

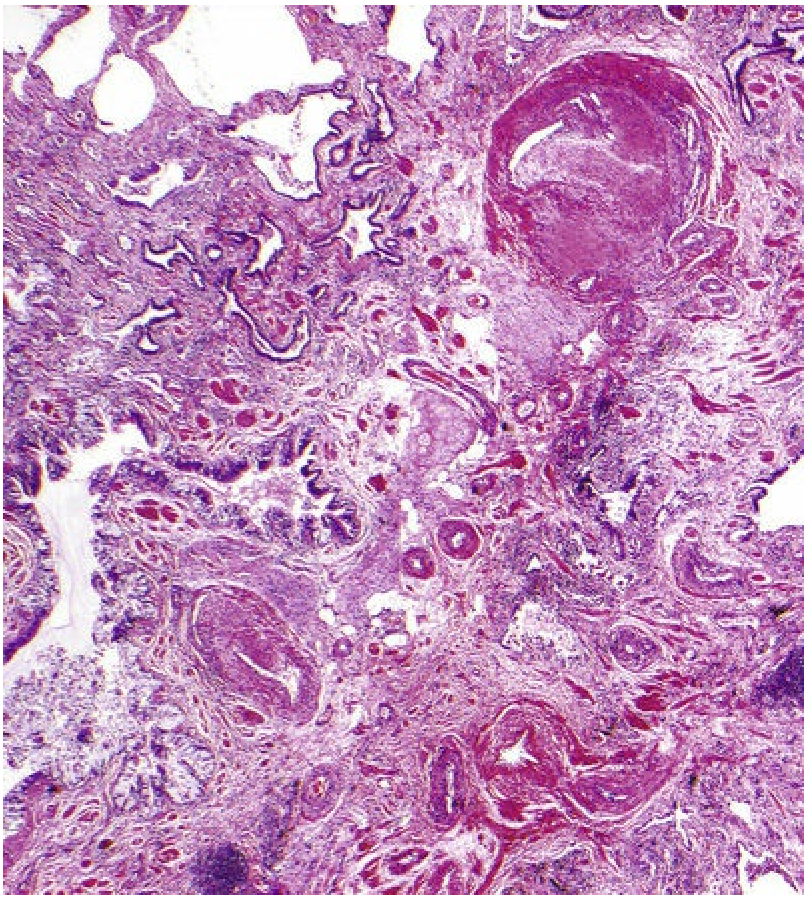

**FIG. 18.37** Absence of the pulmonary artery. The parenchyma lacks pulmonary arteries, but shows very prominent bronchial arteries instead.

Pulmonary stenosis may affect lobar and segmental vessels as well as the main pulmonary arteries, and the narrowings may be multiple. Unilateral absence of a pulmonary artery leads to the lung on that side receiving only a systemic blood supply, either through anomalous systemic arteries or enlarged bronchial arteries. People with isolated unilateral absence may lead a normal life, or symptoms may not arise until adult life; one-third remain completely asymptomatic. Symptoms include pulmonary infection or bleeding from bronchopulmonary anastomoses. Ipsilateral lung tumor and pulmonary hypertension have been reported.[257] Clinically, the condition may be difficult to distinguish from embolic occlusion and obliterative bronchiolitis. The presence of other congenital defects would militate against these, and the absence of mosaic attenuation on CT scan would point away from obliterative bronchiolitis.

It is worth noting an iatrogenic complication related to an abnormal pulmonary blood supply in children with pulmonary valve atresia and supply of the lungs solely by systemic arterial blood. In the surgical procedure of unifocalization, the collateral circulation is used to create an artificial trunk supplying the whole of the lung, which can then be anastomosed to the right ventricle via a conduit. We have reported on children with severe postoperative bronchial ischemia and even total infarction, as a result of excessively vigorous stripping of the bronchial circulation from the airways (Fig. 18.38).[258]

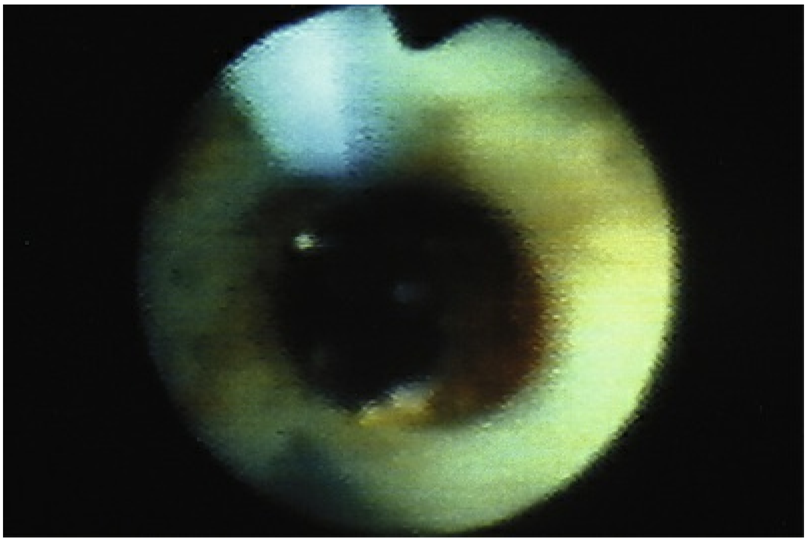

**FIG. 18.38** Iatrogenic complete infarction of the trachea, which is black and necrotic. The child had undergone a unifocalization procedure, in which the bronchial arteries had been stripped from the airways and anastomosed to create a pulmonary trunk. The child is intubated; the blue line marks the endotracheal tube.

One or both pulmonary arteries may originate from the aorta.[259] Bilateral origin from the aorta is part of the spectrum of the common arterial trunk and usually will present to the pediatric or fetal cardiologist. Unilateral origin of a pulmonary artery from the aorta may be an isolated abnormality, sometimes presenting with persistent tachypnea.

## Specific Problems: Congenital

# Disease of the Pulmonary Venous Tree

## Abnormal Pulmonary Venous Drainage

Anomalous pulmonary veins result in blood from the lungs returning to the right side of the heart rather than entering the left atrium. The anomalous veins may join the inferior caval vein or hepatic, portal, or splenic veins below the diaphragm, or above the diaphragm they may drain into the superior caval vein or its tributaries, the coronary sinus, or the right atrium. Anomalous pulmonary venous drainage may be obstructed or unobstructed. The anomaly may be total or partial, unilateral or bilateral, and isolated or associated with other cardiopulmonary developmental defects. These include bronchial isomerism, mirror-image arrangement, asplenia, pulmonary stenosis, patent arterial duct, and a small interatrial communication. The type of isomerism gives a good indication as to whether the anomaly is total or partial; right-sided isomerism suggests totally anomalous veins and left-sided isomerism suggests a partial anomaly. Occasionally, the anomalous vein runs much of its course buried within the lung substance. Anomalous pulmonary venous connections are often narrow, and this may cause relatively mild pulmonary hypertension. Unilateral anomalous venous drainage may be part of complex lung malformations; it may also be seen in association with what appears to be a simple lung cyst. This underscores the need for accurate delineation of all abnormalities even in straightforward-appearing cases. Minor abnormalities of venous connection, such as a segment draining directly into the azygos system, are not uncommon and usually not of practical significance.

The scimitar syndrome is a particular clinical problem characterized by a small right lung, resulting in the heart moving to the right (cardiac dextroposition), and an abnormal band shadow representing the abnormal venous drainage to the systemic veins (Fig. 18.39 and Video 18.4), fancifully compared to a scimitar (a sign that is in fact often absent). Infants with this condition presenting in heart failure have a worse prognosis, often because of associated abnormalities, among which may be malformations in the left side of the heart. Aortopulmonary collaterals should be sought and occluded (Videos 18.5 and 18.6). More invasive treatment options include reimplantation of the vein or pneumonectomy. Severe pulmonary hypertension is an adverse prognostic feature. An association with horseshoe lung has been described; this usually causes early death, but occasional long-term survival has been reported.[260,261]

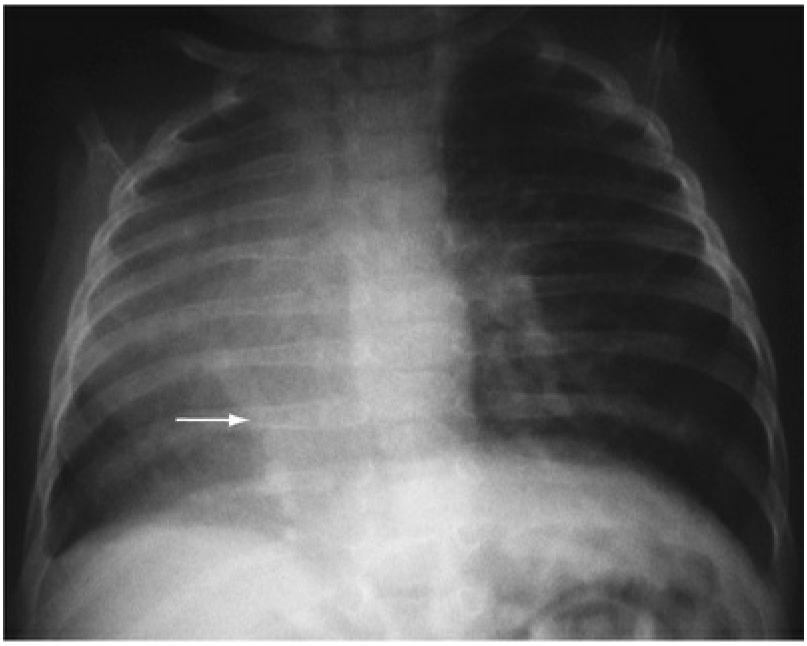

**FIG. 18.39** Scimitar syndrome (congenital small right lung, venous drainage to the inferior caval vein). The abnormal right-sided venous drainage is *arrowed.*

## Congenital Absence of the Pulmonary Veins

Absence of the pulmonary veins or narrowing of their ostia into the left atrium results in pulmonary venous obstruction. It also may be associated with partial anomalous pulmonary venous drainage. The atresia may be unilateral (Fig. 18.40) or bilateral, but in either case severe hypertensive changes develop in both lungs. Congenital pulmonary vein atresia carries a very poor prognosis; few children with the condition survive longer than 1 year. Stenting open the ostia via cardiac catheterization has been reported.

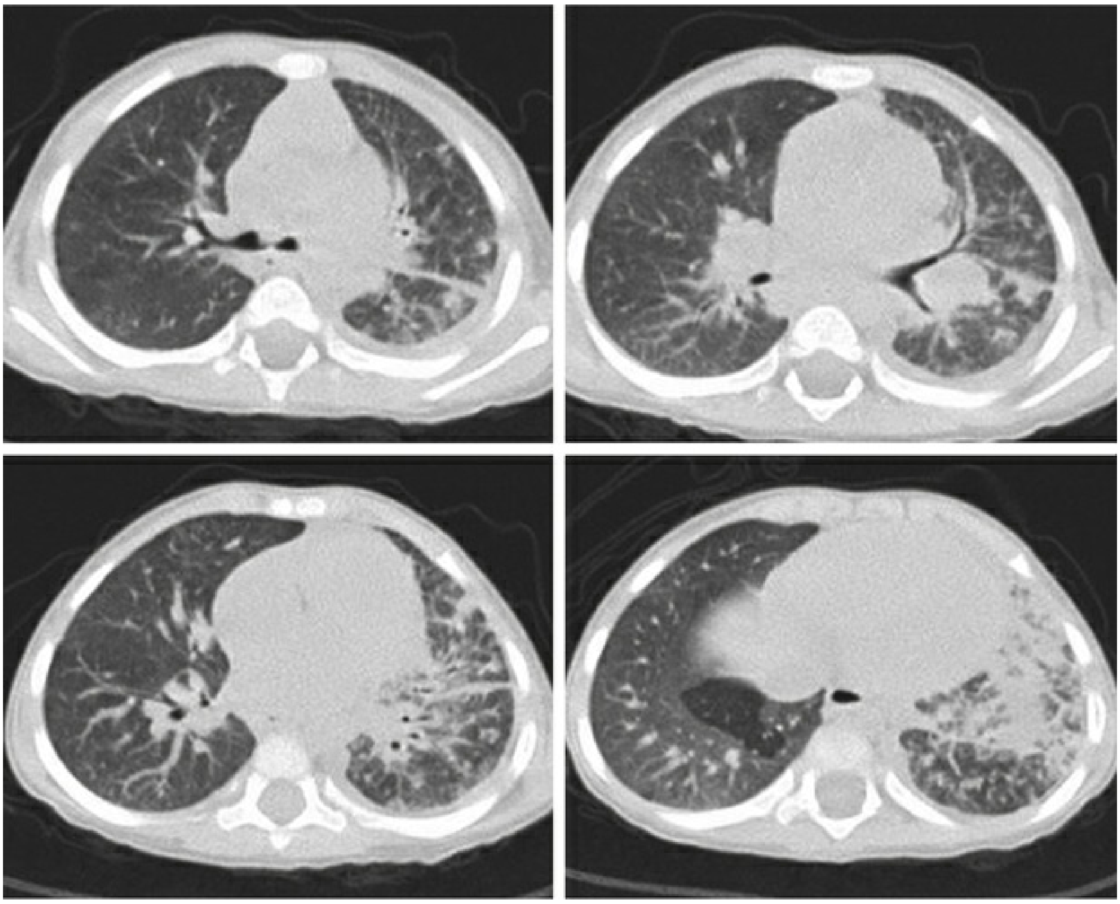

**FIG. 18.40** Computed tomography scan showing changes associated with absent left pulmonary veins. The left lung is engorged, with dilated lymphatics, and a left sided pleural effusion.

# Specific Problems: Abnormalities of the Connections Between the Pulmonary Arterial and Venous Trees

## Congenital Alveolar Capillary Dysplasia

This disorder represents a misalignment of lung vessels due to a failure of capillaries to grow in appropriate number and location within the alveolar tissue of the lung. It was often thought to be associated with abnormally sited pulmonary veins within bronchovascular bundles, but in fact these are dilated bronchial veins with anastomotic connections to the pulmonary veins, which are obliterated beyond these connections.[262] It is an unusual cause of congenital pulmonary hypertension, persistent fetal circulation, and respiratory distress in the newborn. It is discussed in detail in Chapter 56, and will not be further considered in this chapter.

## Pulmonary Arteriovenous Malformations

These have been reviewed in detail recently,[263–265] and include more detailed management protocols than there is space for in this chapter.

### Prevalence

The likely prevalence of significant PAVMs is around 1 in 2630 (95% confidence intervals 1 in 1315–5555).[266] The prevalence of hereditary hemorrhagic telangiectasia (HHT; Osler-Weber-Rendu disease) is 1 in 5000–8000.

### Etiology

Many cases of pulmonary arteriovenous fistulae are associated with HHT, which is a genetic vascular disorder characterized by epistaxis, telangiectasia, and visceral manifestations including PAVMs. The two known disease types, HHT1 and HHT2, are caused by mutations in the endoglin (*ENG,* 9q34) and ACVRL1 (*ALK-1,* 12q13) genes, respectively.[267,268] A third locus has been described on chromosome 5[269] but the exact gene is not yet known. Recently, *SMAD4* (18q21) mutations have been described in HHT with juvenile polyposis syndrome (HHT-juvenile polyposis),[270] and the extending spectrum of these associations reviewed.[271] The unifying feature of these three genes is that they all relate to the TGF-β superfamily signaling pathway.[272] A family with diffuse PAVMs and a mutation in the nuclear prelamin A recognition factorlike (*NARFL,* 21q21.3) has recently been described.[273]

### Clinical Features

PAVMs constitute an important group of abnormalities that potentially involves systemic and pulmonary arterial and venous trees (Fig. 18.41). They represent a direct intrapulmonary connection between the pulmonary artery and vein without an intervening capillary bed. This cavernous arteriovenous aneurysm is an uncommon cause of symptoms in the pediatric age group and is often diagnosed in adults. Presentation is with cyanosis, hemoptysis, chest pain, or neurologic complications (see later). Presentation with breathlessness is rare, and indeed these patients can exercise at a high level, which is related to compensatory secondary polycythemia restoring the blood oxygen carrying capacity.[274] Orthodeoxia and orthostatic tachycardia, if present, are useful pointers to the presence of PAVMs,[275] but relying on this as a screening test will lead to many cases being missed.[276] The chest radiograph may be normal, but more usually well-defined single or multiple opacities are seen, with vessels connecting them to the hila, which are strongly suggestive of the diagnosis. Fistulas occur in the lower lobes in about 60% of cases; they are single in 60% and unilateral in 75%. Macroscopically, lesions can be peripheral or central and may simulate a saccular, cavernous, hemangioma because of aneurysmal swelling. The fistula is fed by at least one afferent artery, usually pulmonary and less often bronchial, and may be drained by several veins, almost always pulmonary. In 80%, there is a single feeding pulmonary artery and a single draining pulmonary vein. There are numerous communications between artery and vein in this tortuous, dilated, wormlike vessel mass. On microscopic examination, the arteriovenous fistula is lined with vascular endothelium.

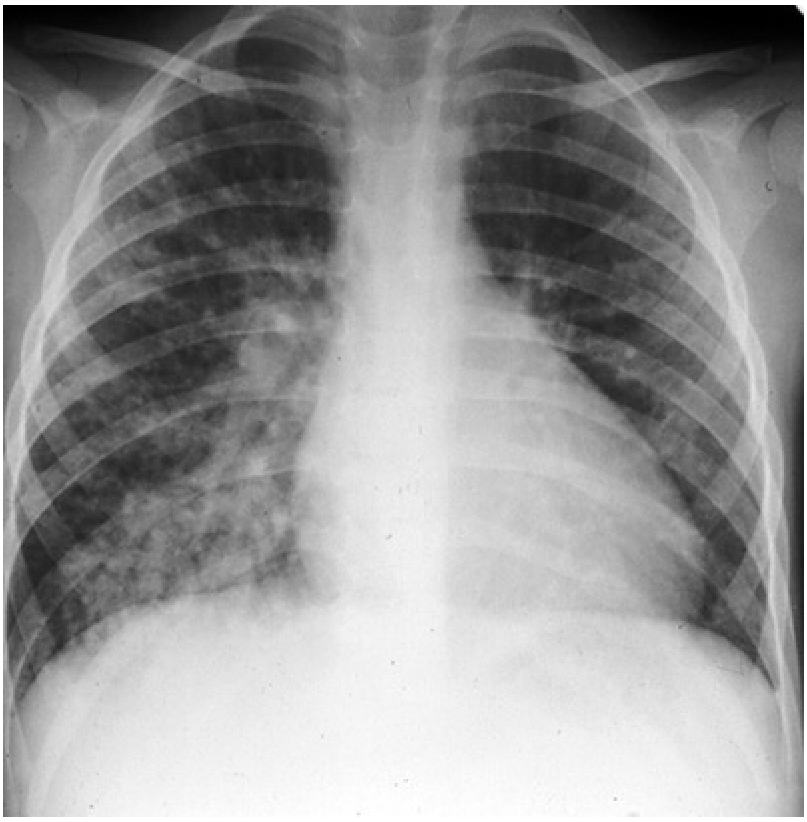

**FIG. 18.41** Chest x-ray showing multiple pulmonary arteriovenous fistulae, in particular in the right lower lobe.

## Diagnosis

Diagnosis is confirmed by documenting an abnormal right-to-left shunt at the pulmonary vascular level, either by contrast echocardiography (the contrast being a peripheral injection of microbubbles), a technetium Tc 99m macroaggregate lung perfusion scan, with shunt quantification by counting over the kidneys and brain, or increasingly using CT angiography. Echocardiography has excellent positive and negative predictive value, and should be the first-line investigation, since it is estimated this approach can substantially reduce the numbers of children requiring CT,[277] and indeed the radiation burden should be a significant factor in the investigation of these patients. The large malformations may have both a systemic and a pulmonary arterial supply (see earlier). The differential diagnosis includes vascular and nonvascular mimics. The former include true and false pulmonary artery aneurysms, and pulmonary varix[263,278]; the latter include any cause of a mass, including a bronchocele and vascular tumors.

## Screening

There are guidelines for screening patients with known HHT,[279] but these are often not well followed.[280] HHT patients who did not have a right to left shunt at diagnosis did not develop one during 5 years' follow-up.[281] A total of 18% of patients with a shunt at baseline increased their shunt in the next 5 years.

## Treatment

When planning therapy, it is important to know if there is a systemic component, since this may cause high-output cardiac failure. Furthermore, embolization of an abnormal pulmonary arteriovenous connection via the feeding pulmonary artery may be curative, whereas more extensive procedures may be needed to deal with systemic arterial components. Embolization of PAVMs is the preferred treatment option with a feeding artery ≥3 mm,[282] even if they are extensive. Various devices, including the Amplatzer, have been used.[283–286] Although lung transplantation has been reported for this condition, the results are clearly inferior. Multiple procedures may be necessary. In one series, one-third of patients obtained normal oxygen saturation and 15% an improved exercise tolerance; generally, embolization, even of major, multiple PAVMs is preferable to transplantation.[287] Regrowth or de novo PAVMs are not rare,[288,289] so repeated echocardiographic screening is wise.[290] Diffuse microscopic disease is more difficult to treat, but there is some evidence that embolization may reduce the prevalence of neurologic complications. The molecular pathology has recently been reviewed.[291]

## Associated Disorders

HHT is associated with AVMs in the brain and elsewhere. A recent meta-analysis[292] reported a prevalence of cerebral lesions around 10% with no gender difference, greater in HHT-1 (13.4%) than HHT-2 (2.4%); more than half were symptomatic. Conversely, PHT and PAVMs with liver disease were more common in HHT-2.[293]

Complications include PAVMs, pulmonary hypertension secondary to high output cardiac failure with systemic AVMs, and primary pulmonary hypertension.[294] The extent to which screening should be performed for cerebral AVMS is controversial[295,296]; but this issue and other aspects of the multisystem management of the condition are beyond the scope of this chapter. PAVMs have been described in association with telomere biology disorder and dyskeratosis, some with germline *TINF2* mutations.[297,298] An association with Birt-Hogg-Dube syndrome has also been described.[299] PAVM may be the first diagnosis, before manifestations of dyskeratosis. The associations with liver disease syndrome[300,301] and after Fontan surgery[302,303] are well described.

### Complications

Complications of PAVMs are related to the bypassing of the filtration function of the pulmonary circulation, and hyperviscosity due to the polycythemia secondary to systemic arterial hypoxemia. Pulmonary hypertension does not usually develop with isolated PAVMs, because there is no alveolar hypoxemia. The patient may develop systemic, in particular cerebral, abscess, or thrombosis. Cerebral complications are especially seen with larger malformations.[304,305] Particular care is needed during prolonged periods of immobility in the patient with hyperviscosity. If the child is treated before puberty, further embolizations may be needed for recurrence of PAVMs after the pubertal growth spurt. In one study, iron deficiency was found to be a risk factor for ischemic stroke,[306] possibly via an effect on platelet aggregation. Whether correction of iron deficiency reduces the risk has not been determined, but it would seem sensible to prescribe iron supplementation in iron-deficient PAVM patients

## Capillary Malformations

These are only recently acknowledged as a clinical entity. They may be isolated, or part of syndromes, such as Sturge-Weber, Klippel-Trenaunay, and Parkes-Weber. They are also associated with macrocephaly and with diffuse overgrowth, and are, in effect, capillary level AVMs.[307–311]

# Specific Problems: Congenital Disease of the Lymphatic Tree

This tree is the hardest to delineate, and in most malformations it will not be relevant. Lymphatic tree disorders usually require histologic confirmation. Lymphatic hypoplasia of varied distribution underlies the yellow nail syndrome in which lymphedema is accompanied by discoloration of the nails and pleural effusions.[312] Though inherited, it may not manifest until adult life. The Klippel-Trenaunay syndrome, usually characterized by varicosities of systemic veins, cutaneous hemangiomas, and soft tissue hypertrophy, is another congenital disorder in which pleuropulmonary abnormalities are described, including pulmonary lymphatic hyperplasia, pleural effusions, pulmonary thromboembolism, and pulmonary vein varicosities. Congenital chylothorax is described in Chapter 69.

Congenital pulmonary lymphangiectasia may be either secondary to obstruction to pulmonary lymphatic or venous drainage, or a primary disorder—the latter either limited to the lung or part of the generalized lymphangiectasia. There is a high association of primary pulmonary lymphangiectasia with other congenital abnormalities, particularly asplenia and cardiac anomalies. It is a rare cause of fetal hydrops,[313] and some cases are related to *PIEZO1*[314] and *FOXC2* mutations.[315] It usually causes severe respiratory distress and has been generally thought to be fatal in the neonatal period, but milder cases with prolonged survival have been described, and indeed presentation may be delayed until adult life.[316,317] The radiological features are also variable, depending on the age of presentation.[318] The lungs are heavy, with widened interlobular septa, and on the visceral pleural surface there is a pronounced reticular pattern of small cysts that accentuates the lobular architecture of the lungs. The cysts measure up to 5 mm in diameter and are situated in the interlobular septa and about the bronchovascular bundles. Near the hila of the lungs, the cysts are elongated. Microscopy confirms that the cysts are located in connective tissue under the pleura, in the interlobular septa, and about the bronchioles and arteries. Serial sections show that they are part of an intricate network of intercommunicating channels that vary greatly in width and are devoid of valves. The cysts are lined by an attenuated simple endothelium. The absence of multinucleate foreign body giant cell reaction distinguishes this condition from interstitial emphysema. The clinical history is also usually quite different; interstitial emphysema is usually (but not invariably, above) a complication of positive pressure ventilation in a very preterm infant. There is increasing interest in treating pulmonary lymphatic disease by techniques of lymphatic embolization.[319] The whole topic is reviewed in detail elsewhere.[320]

# Specific Problems: Congenital Disorders of the Chest Wall

## Congenital Disorders of the Chest Wall

Disorders of the bony rib cage and scoliosis are described in Chapter 72. Here we concentrate on diaphragmatic disorders. Disorders of fetal breathing movements are beyond the scope of this chapter, but these are essential for normal lung development. The abdomen is part of the chest wall, and any disorder that increases abdominal contents before birth, such as fetal ascites or a large tumor, will impede lung development and cause bilateral CSL.

Chest wall disease, such as diaphragmatic hernia and asphyxiating thoracic dystrophy, present as respiratory distress with difficulty in establishing ventilation. By contrast, neuromuscular disease, such as severe spinal muscular atrophy or myotonic dystrophy with maternal inheritance, is characterized by inadequate or absent respiratory effort, but ease of establishing ventilation, unless there are associated unilateral or bilateral CSLs. This last group of conditions is covered in Chapter 72.

## Congenital Diaphragmatic Hernia

This subject has been comprehensively reviewed recently.[321]

### Etiology

This is obscure, and a full review is beyond the scope of this chapter. Genetic studies have recently been reviewed.[322,323] More recent candidate genes include *HLX* gene at chromosome 1q41-1q42,[324] dispatched 1 (DISP1),[325] FGF receptor-like 1 (FGFRL1),[326,327] t-complex-associated-testis-expressed 3 (TCTE3),[328] which is interestingly also found in ciliary outer dynein arms. Animal models suggest that nitrofen-induced reduced cellular proliferation in the developing diaphragm may be important,[329] although it is possible that the primary abnormality may be maldevelopment of the ipsilateral lung.[330] There is a wide variety of abnormalities associated with CDH, including aneuploidy, in particular trisomies 18 and 13, genetic syndromes, and structural abnormalities.[331,332] Many of these will result in a stillbirth or the pregnancy being terminated, so isolated CDH is much more common in neonates. Anomalies associated with CDH include neural tube defects (e.g., myelomeningocele), cardiac defects, and midline anomalies, such as cleft lip and palate. Genetic syndromes, such as Fryns syndrome, can account for up to 10% of cases in some series.[331]

## Pathologic Anatomy

A total of 80% of CDHs are left-sided, through the left pleuroperitoneal canal. Bilateral CDHs are rare. The defect is within the diaphragm itself; there is usually no associated membranous sac. The diaphragm itself may be well developed or significantly deficient, especially at its origin from the 12th rib. Intestine, stomach, liver, and spleen may all herniate into the chest. A nonmuscular membranous sac is present in 10%–15% of cases, signifying the early occurrence of this lesion before closure of the pleuroperitoneal canal.

## Postnatal Presentation

The diagnosis of CDH is usually made antenatally. From birth, infants may present with a variety of symptoms and signs. The herniation of abdominal contents into the chest inhibits normal lung development, resulting in pulmonary hypoplasia,[332] which, in isolated lesions, is the main cause of death. Typically, the abdomen is scaphoid (Fig. 18.42), the chest funnel-shaped, the trachea and mediastinum deviated to the contralateral side. The infant may be entirely well or suffer from several problems ranging from choking episodes to apnea to acute respiratory failure. Rare late presentation may be associated with chronic gastrointestinal symptoms.[333] The diagnosis of CDH is confirmed by a plain radiograph of the chest and abdomen (Fig. 18.43), after the passage of a nasogastric tube. The plain film is a poor indication of the degree of pulmonary hypoplasia.[334] If doubt persists, then an ultrasound scan of the chest demonstrating intrathoracic intestinal peristalsis is helpful. An echocardiogram should be performed to exclude intracardiac anomalies; however, fetal echocardiography should have been part of the antenatal diagnostic work-up. The postnatal differential diagnosis of CDH is similar to the prenatal one and includes extensive congenital cystic disease of the lung, Morgagni anterior diaphragmatic hernia, paraesophageal hiatus hernia, and eventration of the diaphragm.

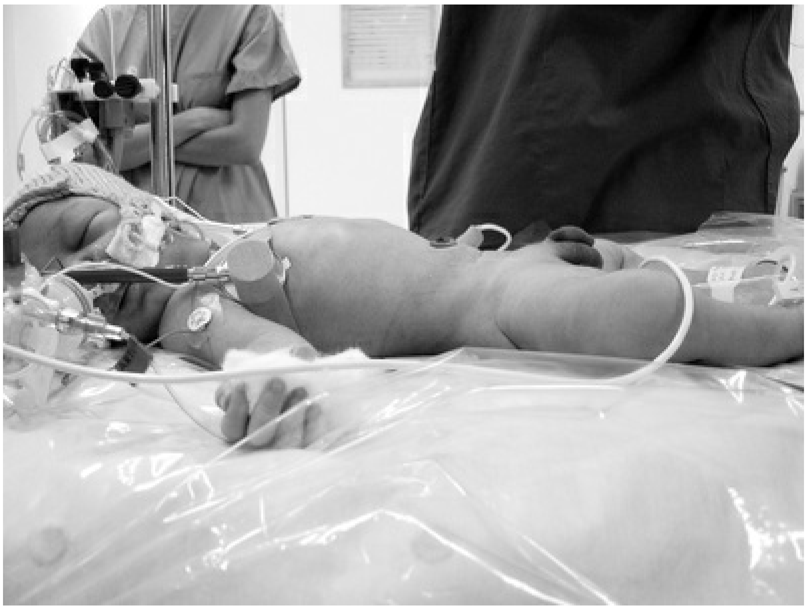

**FIG. 18.42** Scaphoid abdomen in congenital diaphragmatic hernia.

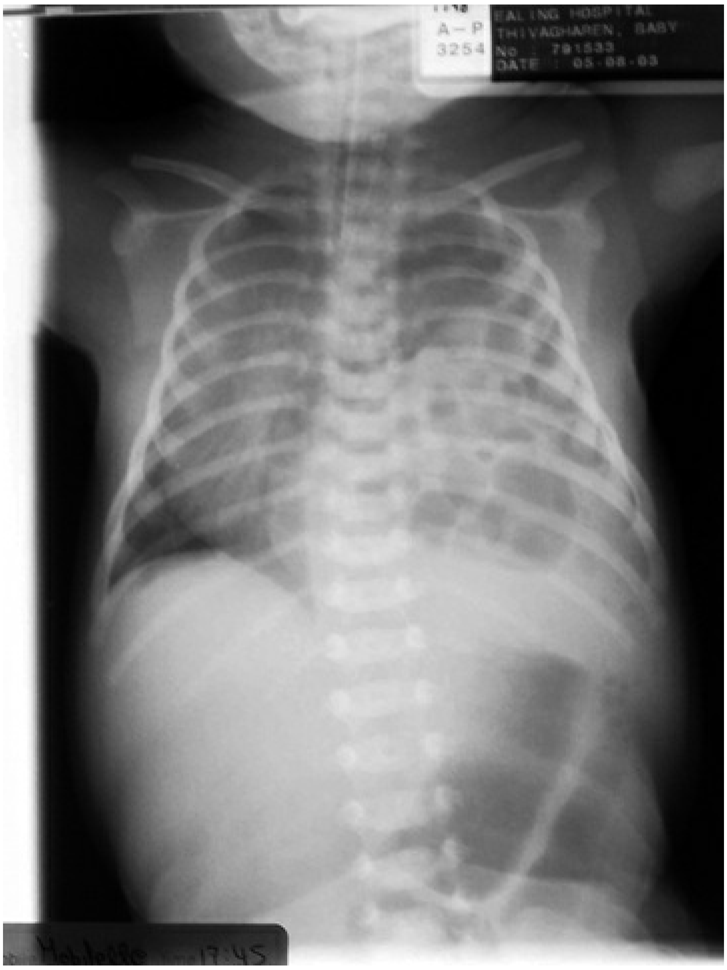

**FIG. 18.43** Plain x-ray demonstrating left-sided congenital diaphragmatic hernia. There are obvious gas-filled loops of bowel in the chest.

## Surgery

The management of CDH is no longer regarded as a surgical emergency. The initial management is to stabilize the baby and optimize respiratory function. Delayed surgical repair has become generally more accepted, with lower mortality rates than have been seen with immediate repair. The exact timing of surgery remains controversial. Many studies have reported varying periods of delay before surgery. One of the principal advantages of this strategy has been related to pulmonary artery pressures falling toward more normal values.[335] The operative repair may be by thoracotomy, or by subcostal or transverse abdominal approaches. The advantage of an abdominal approach is that it permits identification and correction of an associated intestinal malrotation. The laparoscopic repair of CDH has been described.[336] The principle of repair is the same as with any other hernia: reduction of herniated viscera, identification and excision of any hernia sac, and repair of the defect. Usually, primary repair can be achieved following adequate mobilization of the defect's margins. Occasionally, this is not possible because the size of the defect prevents primary suture repair. In these circumstances, a prosthetic patch may be required. An autologous muscle flap is preferred by many surgeons.[336] If extracorporeal membrane oxygenation (ECMO) therapy is anticipated, then some surgeons would prefer to minimize any dissection to reduce the risk of postoperative bleeding secondary to anticoagulation for ECMO. In these circumstances, the mobilization of the defect margins is less and the use of prosthetic patches is greater. For the same reason, malrotation will not be corrected. An intercostal chest drain is placed in the ipsilateral hemithorax by some surgeons to drain any subsequent pneumothorax or chylothorax. However, the negative pressure associated with such a device has been reported to increase barotrauma to the hypoplastic lung,[337] so some surgeons will leave the drain *in situ,* only to have negative pressure applied in the event of an accumulation that requires drainage. A thoracoscopic approach to the repair of CDH has been described. Individual centers describe the only relative contraindication to this approach as being the use of ECMO.[338] Longer operation times and higher recurrent hernia rates have been described, leading the authors to advocate for the routine use of larger wider prosthetic patches rather than primary repair of CDH. These findings have been confirmed in the most recent and wide-ranging literature review of this surgical option,[339] leading the authors to advocate a registry and review of this technique for further assessment. The need for registries and long-term follow up is a recurring theme in this field.

Chylothorax complicating repair of CDH is well recognized. It may be a persistent complication associated with significant morbidity. Octreotide has been advocated in the management of this complication.[340] In this and other causes of chylothorax, placing a thoracoabdominal shunt might be considered.[341]

## Outcome

Survival of neonates reportedly varies between 39% and 95% after repair of CDH. The large variation in mortality reflects the varying severity of the pulmonary hypoplasia and abnormal pulmonary vascularity, as well as variations in the period and technique of preoperative stabilization, perioperative and postoperative mechanical ventilation, and the use of ECMO. If ECMO has to be used, the outlook is not good. Only about one-third of patients thus treated survive to 1 year of life, and substantial comorbidity (respiratory, gastrointestinal, neurodevelopmental) is common.[342] Stege and colleagues have demonstrated that the survival of this condition within one well-circumscribed geographic locus has remained unchanged over 11 years, despite the advent of new therapies. The mortality increased with the presence of other malformations.[343] A variety of neurologic abnormalities, including motor and cognitive anomalies, as well as gastroesophageal reflux, foregut dysmotility and skeletal anomalies, have been reported in infants surviving management of this condition.[344] Significant respiratory and nutritional problems associated with gastroesophageal reflux can occur but often tend to improve with time. Respiratory findings reported in survivors include a range of abnormalities on imaging, from a completely normal examination to ipsilateral lucency on the chest radiograph. Lung function may be normal, or there may be obstructive or restrictive disease. V/Q scans are invariably abnormal. Bronchial hyperreactivity is also described, but the pattern of challenge testing suggests distal airway dysfunction rather than airway inflammation. It is suggested that most of these functional abnormalities relate to the intensity of ventilation in the perioperative period, rather than the degree of pulmonary hypoplasia at birth. However, pulmonary hypoplasia is obviously a critical determinant of survival. The incidence of gastroesophageal reflux has been reported as higher in those diaphragmatic hernias that were repaired directly.[345] Postoperative failure to thrive due to gastroesophageal reflux and oral dysfunction is common. The overall outcome of the condition is known to be worse when it is found to occur within certain syndromes, such as Fryns.

## Anterior Diaphragmatic Hernia

Anterior diaphragmatic hernias occur through the foramen of Morgagni (Fig. 18.44)—a potential space that transmits the internal mammary artery, lying between the sternal and costal attachments of the diaphragm. They are much rarer than Bochdalek hernia and tend not to present in the neonatal period. If unilateral, they occur more often on the right than the left, and are almost always associated with a hernial sac. Often, these hernias are bilateral, and the hernial sacs may communicate with each other or with the pericardium.[346] Anterior diaphragmatic hernias may occur as an isolated morphologic malformation, but are often associated with cardiac anomalies and are the diaphragmatic defect associated with the pentalogy of Cantrell. The principles of repair are similar to those for Bochdalek hernia. Since the diaphragmatic defect is smaller and more easily repaired, prosthetic patches or autologous grafts are required far less frequently than with Bochdalek's hernia. Abdominal and thoracic approaches have been described for open repair.[347] Laparoscopic repair is also well established.[348] The long-term outcome following repair is excellent, and is principally determined by the nature of any associated anomalies. There may be mild airflow obstruction and bronchial hyperreactivity to methacholine, possibly related to distal airway dysfunction. Chest asymmetry and scoliosis are not uncommon.

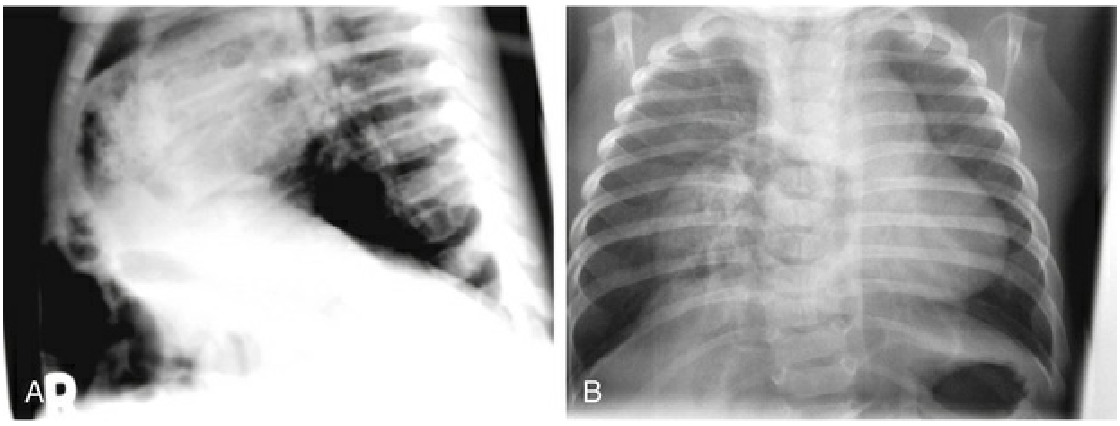

**FIG. 18.44** (A) Lateral and (B) posterioranterior chest radiograph showing a Morgagni hernia.

## Diaphragmatic Eventration

Eventration of the diaphragm may be congenital or acquired (Fig. 18.45). The congenital lesion is far rarer than the acquired one, which is most often either an injury to the phrenic nerve acquired during difficult instrumental delivery, insertion of a chest drain for a pneumothorax, or cardiac surgery. Should the lesion result from difficult, often breech delivery, then it may be associated with Erb palsy. The congenital lesion results from an incomplete development of the muscular portion of the diaphragm or its innervation. This has been described in neonatal cases of fetal rubella and cytomegalovirus infection. The defect is more common on the left than the right side and usually presents as a moderate to complete thinning of the diaphragmatic muscle fibers. In extreme cases, it may be very difficult pathologically to differentiate the lesion from a CDH. Bilateral lesions are rare. Several associated anomalies have been described with the congenital form of diaphragmatic eventration: rib and cardiac anomalies, renal ectopia, and exomphalos. Presentation is usually a chance finding on a chest radiograph taken for other purposes. The diagnosis is confirmed by ultrasound examination demonstrating paradoxical movement of the diaphragm. Usually, no treatment is needed, and the radiologic appearance improves with time. Bilateral large eventrations may need repair, and the best approach is through the chest, followed by radial incision and plication of the diaphragm using nonabsorbable sutures.

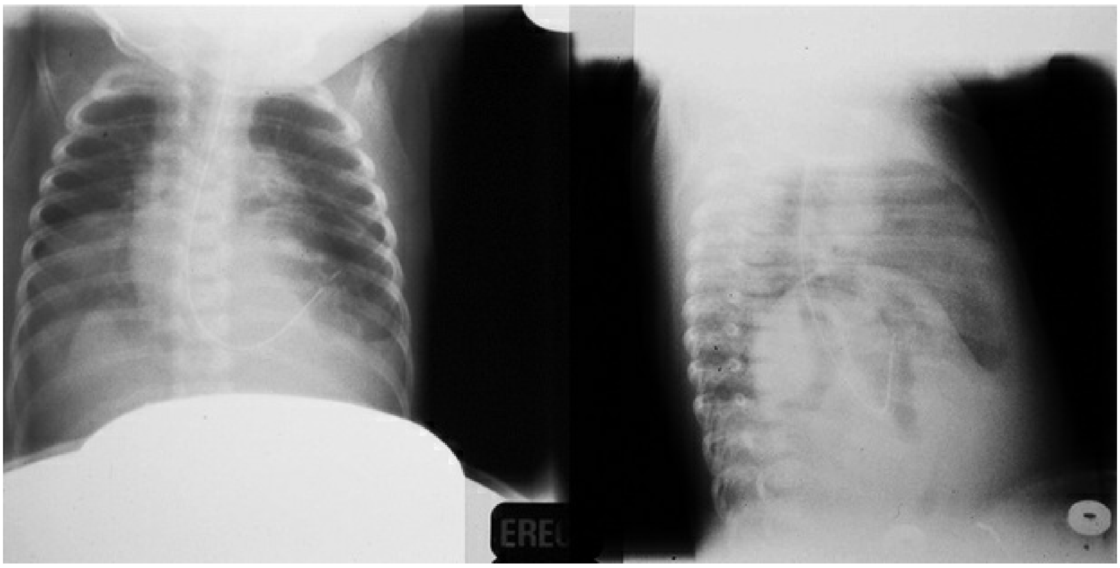

**FIG. 18.45** Bilateral eventration of the diaphragm.

## Specific Problems: Congenital Cardiac Disorders

Cardiac malformations may be coincidental to or a fundamental part of a pulmonary malformation. They are sufficiently common that echocardiography should be a routine part of the work-up of most suspected congenital lung abnormalities. Coincidental malformations are seen with, for example, CLHL. Around 10% have an atrial or ventricular septal defect. Lung abnormalities in which heart disease is fundamental include those with the pulmonary atresia spectrum (see earlier). By definition, lung blood supply is abnormal. However, these cases usually present to the pediatric cardiologists and are beyond the scope of this chapter. It should be noted that vascular compression of the airways in the setting of congenital heart disease is not uncommon and may be referred to the pediatric pulmonologist. The pulmonary complications of congenital heart disease are reviewed in Chapter 39.

## Specific Problems: Multisystem Congenital Disorders That Affect the Lung

Most congenital lung abnormalities are isolated, but a few are part of a more generalized disorder. Tuberous sclerosis may affect the lung as well as the kidneys, heart, and brain. Complex abnormalities of lung development may be associated with chromosomal abnormalities. Micronodular type II pneumocyte hyperplasia is largely—though not exclusively—confined to patients with tuberous sclerosis, of which it is a particularly rare manifestation. It is a multifocal microscopic lesion that usually has no clinical significance, but in rare cases the lesions are of an appreciable size and so numerous that pulmonary function is compromised and the patient complains of breathlessness. The hyperplastic cells show no atypia and appear to be devoid of any malignant potential. Micronodular type II pneumocyte hyperplasia may be seen in otherwise normal lungs or in association with pulmonary lymphangioleiomyomatosis. Unlike lymphangioleiomyomatosis, it affects tuberous sclerosis patients of both sex, and the hyperplastic type II cells fail to stain for HMB-45.

Rare metabolic diseases may affect the lung. These include Niemann-Pick, and lysinuric protein intolerance. They also enter the differential diagnosis of pediatric interstitial lung disease (see Section 6).

# Role of Specific Investigations

This section discusses possible investigations and their role, and does not imply that all should be performed on every child. A selective approach is essential.

## Chest Radiography

All infants in whom any suggestion of a lung malformation has been made antenatally will require a chest radiograph before discharge. In many it will be normal, but subsequent, more detailed imaging, may reveal even quite large malformations. Specific points in the chest radiograph in the context of congenital lung disease include the determination of bronchial (and where the gastric bubble is visible, abdominal) situs and the side of the aortic arch (Fig. 18.46); a right-sided arch may be a normal variant of no concern, but may give a clue to the presence of a vascular ring.[349] A normal chest radiograph does not exclude a significant CTM (above).

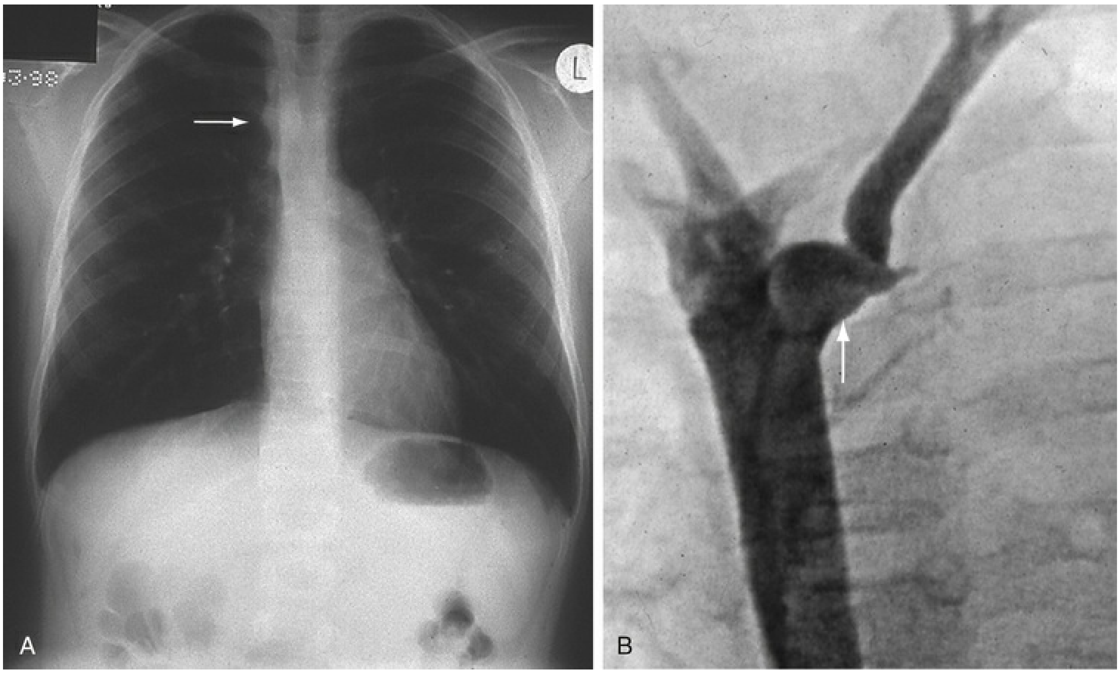

**FIG. 18.46** Vascular ring. (A) Right-sided aortic arch *(arrowed).* Note the tracheal compression by the associated vascular ring. (B) Digital subtraction angiogram showing a right-sided aortic arch, with aberrant origin of left subclavian artery from a diverticulum of Kommerel *(arrow).* A left-sided ligamentum arteriosum completed the vascular ring.

## Ventilation: Perfusion Scanning

Although this technique gives useful functional information, in general its use in investigating congenital lung disease is declining as CT and MRI increasingly give better anatomical and functional images. Unilateral absent perfusion and ventilation is seen in the complete absence of one lung. Unilateral absence of perfusion, which may be combined with secondary abnormalities in ventilation, is seen in the unilateral absence of the pulmonary artery, the unilateral origin of the pulmonary artery from the aorta, and the unilateral absence of the pulmonary veins. Bilateral absent or greatly reduced perfusion is seen in common arterial trunk ("truncus arteriosus"); the pattern of ventilation is normal. Focal defects are seen with large CTMs. Increased uptake of radiolabeled microspheres given by peripheral vein injection is seen in the brain and kidneys as a feature of PAVMs (as well as in congenital heart disease with right-to-left shunt) and has been used to quantitate shunt. Split lung function may be useful in determining whether operation on a unilateral bronchial or pulmonary artery stenosis is advisable. In cases of doubt, V/Q scanning can differentiate CLHL from hyperinflation of a normal lobe secondary to contralateral CSL or lobar atelectasis; in this case, the lucent area is functional, whereas congenital lobar emphysema causes a filling defect.

## Ultrasound Scanning (Including Echocardiography)

Cardiac abnormality is so important when considering congenital lung malformations that it is wise to include an echocardiogram as part of the investigation of many if not most infants with suspected congenital lung disease. Indeed, fetal ultrasound will have already detected many cardiac abnormalities. Echocardiography detects relevant abnormalities of the systemic arteries in the mediastinum, such as the double aortic arch and the aberrant origin of subclavian artery. The pulmonary arteries and veins should be imaged, and unilateral abnormal (hemianomalous) venous drainage excluded. Injecting saline into a peripheral vein allows detection of a right-to-left shunt; in such cases, bubbles appear in the left atrium. Pulmonary artery pressure may be estimated from the Bernoulli equation if there is physiologic tricuspid or pulmonary regurgitation. It may be possible to image abnormal collateral arteries arising from the abdominal aorta. Parenchymal ultrasound imaging is generally less helpful. Defects in the diaphragm may be identified and pleural disease confirmed. Ultrasound is useful in differentiating thymic abnormalities from mediastinal cysts.

A further use for this technique is endobronchial ultrasound, performed by skilled pediatric interventional radiologists, to determine if there are any complete cartilage rings in the major airways.

## Computed Tomography

CT gives the best images of parenchymal abnormalities and is currently probably the first investigation of choice in an adult with suspected CTM. A cystic CTM large enough to have the potential to be infected may be invisible on chest radiographs, so CT is recommended for all infants in whom an antenatal diagnosis of a lung malformation has been made, even if the chest radiograph after birth appears normal. Scanning after contrast injection, especially using modern reconstruction techniques, may delineate abnormal aortopulmonary collaterals, obviating the need for angiography (Fig. 18.47). This is the investigation of choice for imaging a vascular ring (see Chapter 39).

cranially to drain into the azygous system. (D) The CTM is supplied by collaterals arising from the aorta below the diaphragm. (E) Note the venous drainage *(blue arrow)* lying behind the aorta *(red arrow).*

## Magnetic Resonance Imaging

As discussed above, fetal MRI is often used to delineate congenital thoracic abnormalities, but there is currently insufficient evidence to recommend that this technique be widely adopted clinically. At present, postnatal MRI requires general anesthesia in small children, but the lack of radiation exposure and ability to reconstruct vascular anatomy make this an attractive technique. MRI is the best way of detecting extension of a neurogenic tumor into the spinal canal. It can also be used to image any airway compression and its cause, and also to delineate systemic and pulmonary vasculature.

## Barium Swallow

A barium swallow investigation may be used in this context to diagnose a vascular ring (Fig. 18.48), but increasingly its use is superseded by CT or MRI angiography. However, esophageal compression and hold-up of contrast may be used to confirm that the abnormality is causing dysphagia *(dysphagia lusorum),* which may be particularly useful if the vascular anatomy is of uncertain significance (anomalous subclavian artery, which may be a variant of no consequence). It is also worth considering a bronchoscopy to assess any airway compression in this anomaly. A barium swallow cannot rule out an H-type tracheoesophageal fistula.

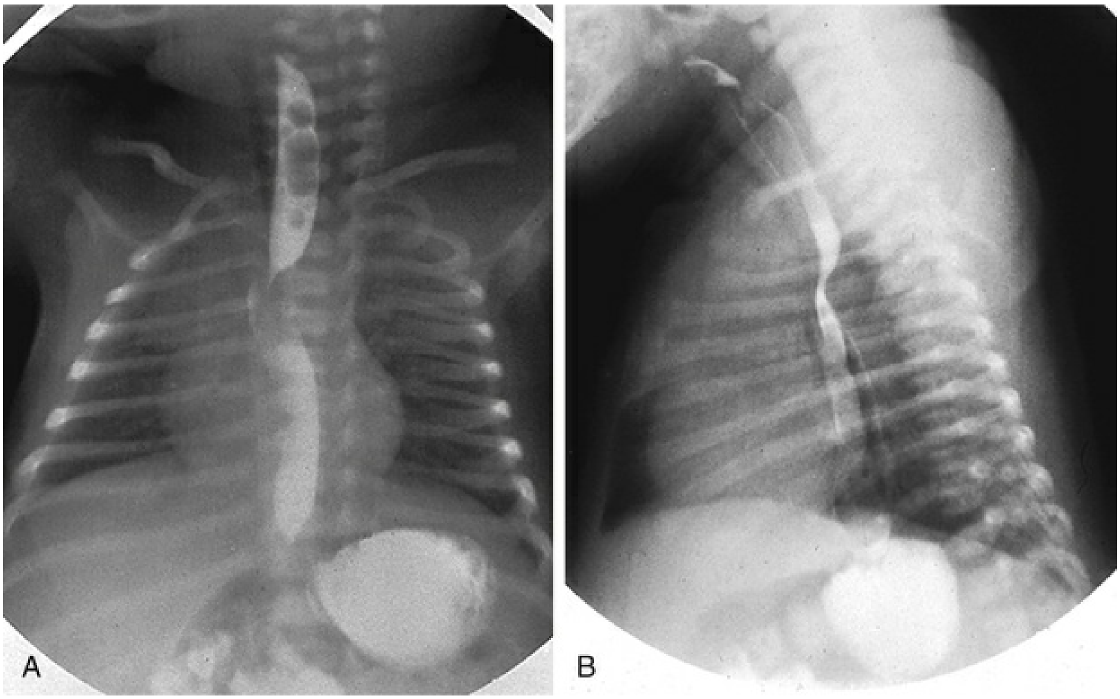

**FIG. 18.48** Barium swallow showing the indentation of a vascular ring (double aortic arch). (A) Posterioranterior view. (B) Lateral view.

## Esophageal Tube Injection

Abnormal connections between the esophagus and the trachea or a CTM are best delineated by a tube esophagram. The pressure injection of barium will reveal a connection that a simple barium swallow will miss. This investigation is only needed in selected cases of CTM, in which either the malformation is close to the bronchial tree, or severe infection (particularly anaerobic) is a feature. Bronchoscopy may also delineate a fistula.

## Angiography

In complex cases, angiography may be necessary before surgery. However, the increasing use of CT and MRI to delineate vascular anatomy means that invasive investigation is now needed much less often, and really only as part of therapeutic embolization. The operator must completely delineate the anatomy of the pulmonary and systemic trees, including establishing whether there are any arterial collaterals (see earlier). It should be remembered that a CTM may be supplied from the coronary, internal mammary, intercostals, or subclavian arteries. At the same time, any embolization that might be indicated can be performed, including occlusion of PAVMs and systemic arterial collaterals (Fig. 18.49 and Videos 18.5▶ and 18.6▶). This may be the only treatment required, or the occlusion of large aortopulmonary collaterals to a CTM may make subsequent surgery safer. It should be stated that the role of embolization in congenital disorders of the lung, other than for pulmonary arteriovenous fistula, is controversial.

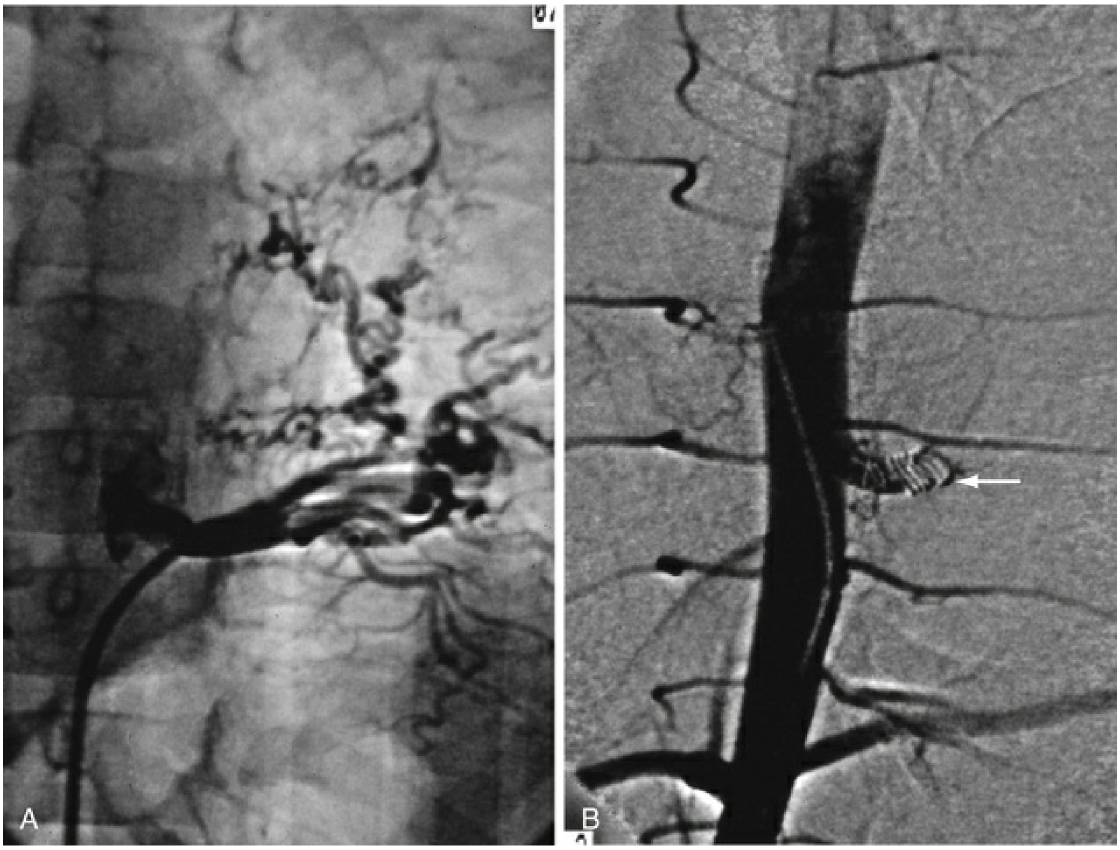

**FIG. 18.49** Digital subtraction angiogram before (A) and after (B) coil embolization of a large aortopulmonary collateral, supplying a cystic congenital thoracic malformation in the left lower lobe. The *arrow* (B) points to the site of the coil occlusion.

## Bronchoscopy

The anecdotal experience with fetal bronchoscopy has been described above. Bronchoscopy may be performed with either or both a flexible or rigid instrument. Rigid bronchoscopy (MLB) was discussed in detail earlier, and it should be noted that laryngeal clefts may be missed by flexible bronchoscopy. The most clear-cut use of fiberoptic bronchoscopy is in the investigation of stridor. In all but typical cases of laryngomalacia, this investigation should be performed at an early stage. Multiple causes of stridor are not uncommon, and all of the accessible respiratory tract should be examined. Bronchoscopy should not be delayed by performing a series of nondiagnostic imaging studies. In other contexts, bronchoscopy is probably best combined with other procedures requiring a general anesthetic, such as angiography (see earlier). Other than for the investigation of stridor or other upper airway disease, an anesthetic can rarely be justified solely for bronchoscopy in the context of congenital lung disease. Ideally, the flexible bronchoscopy should be performed under general anesthesia via a facemask, so the whole of the airway can be inspected, including the larynx, under conditions of quiet respiration. First, bronchial arrangement can be verified. Second, abnormalities of the bronchial wall, such as complete cartilage rings or compression by a vascular ring, can be ascertained. Finally, the presence of blind-ending bronchial stumps can be determined; these may act as a sump for infection. Another role for bronchoscopy is the assessment of airway narrowing in the case of aberrant origin of the left subclavian artery (see earlier). This may be a harmless normal variant or may cause significant airway narrowing, if a left arterial ligament completes a vascular ring. In doubtful cases, bronchoscopic inspection of the airway is indicated. Finally, H-type fistula may be missed on esophageal tube injection, and only detected by bronchoscopy

## Low Contrast Volume Bronchography

Airway malacia can be visualized directly and further documented by performing a limited bronchogram with a soluble contrast medium (see Video 18.2).[350] Unlike the bronchograms carried out before the advent of CT scanning, the purpose is to delineate the major airways, not to achieve alveolar filling, and only very small volumes of water-soluble contrast are required. This technique is better than flexible bronchoscopy, which may mask the severity of the condition by the inevitable application of positive end-expiratory pressure due to partial airway blockage by the bronchoscope. Low contrast volume bronchography can be used to titrate the CPAP pressures needed to overcome malacic segments.

## Summary and Conclusions

Congenital lung disease can present at any time from 14 weeks of gestation to old age and should at least be considered as part of the differential diagnosis in many clinical situations. The lesions may regress to virtually nothing, require relatively straightforward surgery, or be among the most complex therapeutic challenges encountered. The chief need is for information about the long-term consequences of many of the lesions diagnosed antenatally, so that more precise counseling can be provided. Children with congenital lung disease should be enrolled in registries and followed up in a systematic manner. Another need is for refinement of MRI scanning so it can be performed without the need for general anesthesia and to give more precise information about parenchymal abnormalities to obviate the need for radiation exposure. Finally, we need to progress from a crude descriptive approach to understanding the molecular pathways underlying CTMs. This will require the formation of consortia of interested multidisciplinary teams and basic scientists to move the field forward. Only then will we have an understanding of how normal embryology deviates to produce these malformations, and it is to be hoped that gene signatures will allow us to select high-risk lesions for surgery from those that can be safely left unoperated.

# Respiratory Disorders in the Newborn

*Noah H. Hillman MD, Hugh Simon Lam MBBChir, MD*

Respiratory disorders are the most common reason for admission to a neonatal intensive care unit (NICU) and are a major source of neonatal mortality and morbidity. This chapter describes the etiology, presentation, management, and outcome of neonatal respiratory disorders, as well as the initiation of respiration at birth and resuscitation.

## Initiation of Respiration at Birth

One of the most important and well-coordinated physiologic events in a person's life is the transition from the fetal state to the newborn infant. Within the first minute of life, the newborn must clear the fetal lung fluid from the airways and establish gas exchange. Although most infants complete this transition without problems, inadequate initiation of respiration at birth can be catastrophic to both the respiratory and cardiovascular system.[1]

The human fetus is breathing long before the infant is born, and fetal breathing is necessary for normal lung development. Fetal breathing is detected as early as 12–14 weeks gestational age (GA), and the frequency and duration correspond to the GA and sleep state of the fetus.[2] Fetal breathing and swallowing occur during active sleep, with limited amounts during quiet sleep.[2] During *active* sleep, the fetus has an irregular breathing pattern (20–30 bpm) characterized by long inspiratory and expiratory times with movement of fetal lung fluid into and out of the lung. Central chemoreceptors in the fetus respond to fetal hypoxia with decreased breathing (opposite of newborn physiology) and to hypercarbia by increased breathing and initiation of *active* sleep.[2] Fetal breathing is probably controlled by prostaglandin secretion. Fetal sheep given prostaglandin E2 infusions stop breathing, and treatment with prostaglandin synthetase inhibitors, such as indomethacin, cause continuous fetal breathing.[3] At birth, the rapid onset of regular breathing is likely due to a combination of removal of prostaglandin production from placenta, tactile and cold stimuli from the skin, activation of Hering-Breuer reflexes, and changes in arterial blood oxygenation levels ($PaO_2$).[2,4] Most of term infants (85%) will begin spontaneous breathing by 10–30 seconds of life, with another 10% requiring only drying and stimulation to begin a regular breathing pattern.[5] Most preterm infants <28 weeks and <1000 g (69%) have an audible cry and start breathing immediately after birth.[6]

# Fetal Lung Fluid

The airspaces of the fetal lung are filled with fluid created by the airway epithelial cells. Production and maintenance of the normal volume of fetal lung fluid is essential for normal lung growth. Fetal lung fluid is secreted by the airway epithelium as a filtrate of the interstitial fluid of the lung by the active transport of chloride.[7] The fetal lung fluid is high in chloride but very low in protein and bicarbonate. Although the secretion rate has not been precisely measured in the human fetus, the fetal sheep during the middle of gestation has a secretion rate of about 4–5 mL/kg per hour.[8] Fetal lung fluid flows intermittently up the trachea with fetal breathing because the pressure in the trachea exceeds the amniotic fluid pressure by approximately 1 cm $H_2O$. Intermittent glottis closure *in utero* causes increased fetal lung fluid volume and pressure, and assists with lung development.[9] Abnormal flow and pressure in the lungs during development lead to either lung hypoplasia (e.g., in oligohydramnios) or large dysplastic lungs (e.g., in chronic upper airway obstruction). The fetal lung is fully expanded near term with a fluid volume of about 40 mL/kg, which is approximately twice the functional residual capacity (FRC) of the air breathing newborn.[8] As the pregnancy gets closer to term gestation, the rate of liquid formation and the volume of liquid within the fetal lung decreases.[10]

## Clearance of Lung Fluid From Airways at Birth

The fetal lung fluid is cleared through (1) active transport of sodium by epithelial sodium channels (ENaCs) during labor, (2) mechanical forces during birthing process, and (3) newborn breathing after birth. Although the fetal lung fluid is generated throughout gestation by active secretion of chloride through apical epithelial cells into the airways, in late gestation the number and activity of ENaCs increase and generate a $Na^+$ gradient in the lung's interstitial space. Water follows the sodium out of the airspace through diffusion or through specific water channels (aquaporins). Aquaporins also increase throughout gestation and can be upregulated by antenatal steroids. Increases in fetal cortisol, thyroid hormones, and catecholamines near term gestation contribute to the reversal of fluid movement in the lungs.[11] In preterm fetal sheep, infusion of cortisol and $T_3$ will activate the sodium pump, which normally occurs at term.[12] Exposure to postnatal oxygen tension also increases sodium transport across the pulmonary epithelium. Blockage of or genetic mutations of the alpha-subunit of these amiloride-sensitive ENaCs leads to respiratory failure and death due to inability to clear fetal lung fluid.[13] The critical role of ENaCs at birth has been questioned by the lack of respiratory distress at birth in mice missing the other two subunits of the ENaC.[14] Cyclic nucleotide-gated channels on the type I pneumocytes also assist in Na transport out of cells.[15] Overall, activation of the ENaC assists in fluid clearance from the lungs at birth and throughout life.

Although there is some evidence for a small amount of lung fluid to be cleared during the progression through the vaginal vault, most lung fluid excreted through the nose and mouth, when the infants head is exposed, is due to fetal repositioning and spinal flexion caused by uterine contractions.[10] It is difficult to quantify the percent of lung fluid excreted by these physical mechanisms, but the combined relative contribution to fluid clearance is likely as high as 33% of lung fluid.[16] Elective cesarean sections (C-sections), without labor or rupture of membranes, will not have this physical clearance of lung fluid or activation of ENaCs prior to initiation of breathing.

Even with the reduction of fetal lung fluid volume during late gestation and labor and the expulsion of fluid by spinal flexion, there is greater than 15 mL/kg of fluid in the airways at the time of birth.[1] This fluid is cleared from the airways and driven into the interstitial space surrounding the airway within the first few seconds of life by a few large, negative pressure breaths.[17,18] An FRC is formed following the first breath in normal term infants. Using phase-contrast x-rays, Hooper and coworkers demonstrate that fluid leaves airways during inspiration with some reflooding during expiration (Video 19.1).[1,17] Positive end-expiratory pressure (PEEP) can decrease the backflow of interstitial fluid into airways, improve the uniformity of lung recruitment, and decrease the injury from mechanical ventilation.[1,19] The components of fetal lung fluid then are cleared directly into the vasculature or via lymphatics from the lung interstitium over multiple hours.[20]

## Respiratory Depression at Birth

Although most infants initiate respirations at birth, failure can occur because of fetal hypoxia (birth asphyxia), maternal medications leading to suppression of breathing, congenital malformations, or failure of the central nervous system chemoreceptors. The combination of immature lungs and reduced respiratory drive makes preterm infants more likely to need assistance with breathing at birth.[5] Primary apnea occurs in newborns after birth and often responds to tactile stimulation. *In utero* the fetus responds to hypoxia with decreased fetal respiration thereby decreasing metabolic requirements; thus a severely hypoxic infants will not breath at birth.[21] Many of these infants will respond to stimulation and continuous positive airway pressure (CPAP). Room air (21%) has been shown to be preferable to 100% oxygen and is recommended for the initial resuscitation of the term infant.[5] If the infant in primary apnea is not assisted and hypoxia continues, the infant progresses into secondary apnea, where the heart rate (HR) decreases and responds only to positive-pressure ventilation (PPV). Continued deterioration of blood pressure will follow and metabolic acidosis will develop if respiration is not initiated. PPV through either a face mask or endotracheal (ET) tube should restore cardiopulmonary function in the majority of infants, as less than 1% of infants should need epinephrine in the delivery room.[22] Pulse oximetry is now recommended for any infant suspected of needing resuscitation.[5] Apgar scores, named after Virginia Apgar, are assigned to the infant at 1 minute, 5 minute, and 10 minutes for HR, breathing, color, reflex, and tone.[23] Although a useful guide for how a newborn resuscitation is progressing, there is a high degree of variability in the Apgar scores assigned to infants and color has recently been removed from the algorithm for neonatal resuscitation.[5] Persistently low Apgar scores, especially <5 at 10 minutes, have been associated with higher infant mortality, cognitive delays, increased risk of cerebral palsy and increased educational needs throughout childhood.[24,25] Infants with severe birth asphyxia, metabolic acidosis, and neurologic signs of encephalopathy should receive therapeutic hypothermia.[5] Birth asphyxia can affect all the organ systems and management will be individualized based on laboratory findings.[26]

# Delivery Room Resuscitation

Approximately 10% of infants require some form of assistance at birth; approximately 2% require intubation and PPV, and less than 0.5% require chest compressions and epinephrine.[5,22] The percent of infants requiring resuscitation increases with decreasing GA. Every 5 years, the International Liaison Committee on Resuscitation (ILCOR) reviews all studies on newborn resuscitation and provides treatment guidelines for infants who fail to breathe adequately at birth; the following comments reflect their most recent recommendations from 2015 (Fig. 19.1).[5] The new guidelines stress the importance of the first “golden” minute of life, when breathing should have spontaneously begun or respirations are being assisted. All newborn infants, including nonvigorous ones exposed to meconium, should receive stimulation and drying at birth.[5] Routine oropharyngeal suction should not be done unless the oral pharynx appears occluded. If the infant is not breathing, is gasping, or HR is less than 100 at 30 seconds of life, the infant should receive PPV with PEEP via a T-piece or resuscitation bag. Resuscitation with room air is recommended for term infants, whereas most preterm infants can be resuscitated with 0.21–0.30 fraction of inspired oxygen ($FiO_2$).[5,27] Pulse oximetry should be applied and the oxygen titrated to maintain infants within the normal ranges during the first minutes of life.[28] It should be noted that the fetal $PaO_2$ is low and normal transitional oxygen saturations are not greater than 85% for almost 5 minutes. If after 30 seconds of PPV ventilation, with an initial pressure of 20–25 cm $H_2O$, the HR is not greater than 100, the resuscitator should progress through a series of ventilation corrective steps (i.e., MR.SOPA—**M**ask adjustments/**R**eposition airway/**S**uction and **O**pen mouth and nose/increase **P**ressure/consider **A**lternative airway) and consider intubation of the infant. Intubation should be confirmed by chest rise, condensate in ET tube, improved HR, and carbon dioxide detector (PediCap). If HR remains less than 60 bpm after intubation, chest compressions should be started using a two-handed encircling chest approach.[5] The sternum is compressed approximately a third the diameter of the chest (approximately 2 cm) at a ratio of 3 : 1 for 120 events (90 compressions and 30 breaths) in a minute. Pulse oximetry and a three-lead electrocardiography (ECG or EKG) can be used to help assess the HR. If adequate ventilation and compressions do not return HR greater than 60, then the infant should receive intravenous (IV) epinephrine (0.01–0.03 mg/kg) through an umbilical venous catheter (UVC) or IV catheter. ET epinephrine (0.05–0.1 mg/kg) can be tried until IV access is obtained but has a decreased response rate compared with IV epinephrine.[29] The use of sodium bicarbonate and naloxone are no longer recommended during the newborn resuscitation. Normal saline or group O Rh-negative blood (10 mL/kg body weight) should be given over 5–10 minutes if the infant is hypotensive due to blood loss. If there is no HR and Apgar score is 0 after 10 minutes of adequate resuscitation, it is appropriate to discontinue further resuscitation due to the poor neurologic outcome.[5,29] Because most infants will respond to appropriate ventilation, resuscitators should consider other underlying conditions that might impede ventilation, such as pneumothorax, hypoplastic lungs from oligohydramnios, congenital diaphragmatic hernia (CDH), or other congenital anomalies.

## Resuscitation of the Preterm Infant

The GA of the preterm infant will determine many of the steps taken during resuscitation. The care of late preterm infants (34–37 weeks) often follows the resuscitation guidelines for term infants, but they should be monitored closely after birth due to increased newborn morbidities (jaundice, temperature control, transient tachypnea of the newborn [TTN], feeding). Infants less than 32 weeks have immaturity of most organ systems, with the lungs and brain being the most vulnerable to injury and most likely to affect resuscitation. Antenatal steroids prior to preterm delivery stimulate maturation of many of the organs. Fortunately, more than 90% of preterm infant less than 34 weeks GA will receive some portion of a steroid course prior to delivery and this improves response to resuscitation. The extremely immature brain may have decreased respiratory drive requiring PPV ventilation. Thermoregulation is extremely important for the very preterm infant, due to brain immaturity and lack of brown fat sources, and they ought to be placed in a plastic bag or thermal wrap immediately after delivery.[29]

Lung immaturity has the largest influence on the resuscitation of the preterm infant, and many preterm infants require assistance in the transition from fetal life.[5,29] Lung development, maturation, and the surfactant system are covered extensively in other chapters in this book. Although the lack of labor may lead to increased fetal lung fluid at birth (see earlier), antenatal steroids or the maternal conditions that led to preterm birth may have primed the preterm lung for gas exchange. Although increased surfactant levels are probably not present until closer to 48 hours after antenatal steroids, preterm sheep lungs have decreased thickness of the lung parenchyma by 15 hours (likely due to decreased interstitial fluid) and decreased injury from mechanical ventilation by 24 hours after steroids.[30,31] Surfactant-deficient preterm babies may lack the muscle strength to generate sufficient negative pressure to overcome their compliant chest wall and high airway surface tension.[11] The amount of surfactant stored in type II cells is low in preterm infants not exposed to antenatal steroids, so less is available for secretion in response to birth.[32] Without the assistance of surfactant in reducing surface tension, it is difficult for very small infants to develop an FRC. Since the approval of exogenous surfactant replacement therapy in the early 1990s, there has been a trend towards intubation and treatment of the smallest infants with surfactant.[33] It should be noted that all the surfactant studies were performed prior to the American College of Obstetricians and Gynecologists (ACOG) recommendation for antenatal corticosteroids in 1994, so it is unclear what the results would be in the current era. Multiple studies comparing CPAP and surfactant treatment have been conducted in the past 10 years, and each has shown a trend towards improved respiratory outcomes in the infants receiving CPAP.[34,35] Meta-analysis of all the trials demonstrated approximately a 10% reduction in bronchopulmonary dysplasia (BPD) with early CPAP.[36] Recently it has been recommended to attempt to support preterm infants with CPAP if they are breathing in the delivery room.[5] Remarkably, almost 50% of infants born less than 750 g will be successful on CPAP alone.[37] This is possible because an endogenous surfactant pool size of only approximately 5 mg/kg (5% of term levels) is necessary for preterm lambs to respond to CPAP and lambs with approximately 10% the endogenous pool size have reduced injury from mechanical ventilation.[38] If given the opportunity, the majority of very preterm infants will successfully initiate breathing without extensive resuscitation.[6] Extremely preterm infants that require extensive resuscitation in the delivery room have significant morbidities and increased mortality.[39]

Although there are clear benefits to resuscitation of term infants with room air, the consensus is less clear on the starting oxygen levels for preterm infants. The 2015 guidelines recommend starting preterm infants at a $FiO_2$ between 0.21 and 0.30 and then titrating oxygen based on pulse oximetry.[5] Preterm infants resuscitated with room air often require an increase in $FiO_2$ to maintain saturations.[40] Studies comparing 30%–90% oxygen for preterm infants demonstrated that most infants in the lower oxygen group had an increased oxygen requirement to 40%, whereas the higher group had decreases in oxygen requirements. Eventual oxygen requirements ended up at approximately 30% oxygen in both groups.[41,42]

To overcome the resistance created by the air-fluid interfaces in small airways of preterm infants, physicians have used prolonged inspiratory times, commonly called sustained inflation (SI), to recruit FRC.[17,43–45] In preterm lambs, SI augmented the cardiorespiratory transition at birth and improved the HR response to resuscitation after asphyxiation.[43,46] In a few small human studies, SI at birth decreased the need for mechanical ventilation at 72 hours and may lead to a decrease in BPD.[44,47] In preterm infants, SI generates an average FRC volume recruitment of only 8 mL/kg and lung volume recruitment occurs only in spontaneously breathing infants.[45,48] Adduction of the glottis, a normal fetal occurrence, blocks airflow in the nonbreathing infants.[1,48] Multiple clinical trials are currently underway to determine if clearing airway fluid with an SI to achieve FRC will benefit preterm infants. ILCOR removed the recommendation for three brief SIs (added in 2010) from the 2015 guidelines until results are known.[5]

## Ventilatory Control

Complex networks of respiratory neurons within the medulla and pons generate and regulate the involuntary component of respiratory rhythm.[49] Specifically, studies suggest that this spontaneous inspiratory rhythm originates from pacemaker neurons within the pre-Bötzinger complex, one of the networks of neurons that make up the ventral respiratory group in the ventral medulla.[50,51] The phasic transition from inspiration to expiration is modulated by signals from the stretch receptors in the lungs and airways via the vagus nerves and neurons in the pneumotaxic and apneustic centers of the pons.[51] The rhythm is transmitted to the cervical and thoracic spinal motor neurons that innervate the diaphragm and intercostal muscles. These descending pathways activate the inspiratory muscles while inhibiting the expiratory muscles. Breathing pattern is further influenced by afferents from the forebrain, hypothalamus, central and peripheral chemoreceptors, muscles, joints, and pain receptors. Most areas contain multiple neuromodulators that are partly released from the same neurons, implying that neuromodulation is integrated at many levels.[52]

Several neurotransmitters play important roles in respiratory regulation. Glutamate is an excitatory neurotransmitter that activates receptors involved in generating and transmitting respiratory rhythms to spinal and cranial respiratory neurons. Serotonergic neurons in the medulla oblongata are part of a critical system that modulates autonomic and respiratory effector neurons.[53] The most consistent effect of serotonin (5HT) is to restore a normal breathing pattern after hypoxic or ischemic insult. Opioids (endorphins and exogenous drugs) suppress respiration by peripheral and central actions; the latter are due to suppression of recurrent excitation by glutaminergic input within the primary respiratory network. Both γ-aminobutyric acid (GABA) and glycine are essential for generating respiratory rhythm; they are released by late and postinspiratory neurons and inhibit inspiratory neurons, thus facilitating the transition from inspiration to expiration. Deficiency of glycinergic inhibition in knockout mice results in a slower frequency of breathing.

Central and peripheral chemoreceptors are core components of the chemical regulation of breathing patterns. These chemoreceptors modify respiratory activity in response to changes in oxygen, carbon dioxide, and acid-base balance.[54] The central chemoreceptors are situated near the ventral surface of the medulla, whereas the peripheral chemoreceptors are situated at the bifurcation of the common carotid arteries (carotid bodies) and above and below the aortic arch (aortic bodies). In the fetus the arterial chemoreceptors are active but have reduced sensitivity.[55] The peripheral chemoreceptors are not essential for the initiation of respiration and are virtually silenced when the arterial oxygen level rises at birth. Resetting of the carotid chemoreceptors to hypoxia occurs within 24–48 hours of birth[56]; this may result from changes in dopamine levels. The fetus responds to hypoxia with a suppression of ventilation. The lateral part of the lower pons mediates the hypoxic suppression of ventilation. In response to hypoxia, there is a redistribution of the circulation to favor the heart, brain, and adrenals. This minimizes oxygen consumption and conserves oxygen supplies for vital organs. The newborn has a biphasic response to hypoxia, a transient increase in minute ventilation followed by a decrease to or below baseline levels. The initial increase in ventilation may be due to activation of peripheral chemoreceptors and reconfiguration within the pre-Bötzinger complex leading to a change from eupneic rhythm to a gasping pattern.[57] The subsequent reduction in ventilation may result from a fall in carbon dioxide tension following the initial hyperventilation or the suppressant effect of hypoxia, which occurs in the fetal state and persists into the neonatal period. Very immature infants respond to hypoxia by becoming apneic, which is like the fetal response. The biphasic response to hypoxia disappears by 12–14 days, and the adult pattern is subsequently observed (i.e., stimulation of breathing without depression). However, an animal model suggests that the acute hypoxic ventilatory response of an individual could be attenuated by exposure to sustained hypoxia followed by chronic intermittent hypoxia during the neonatal period.[58] In contrast, exposure to hyperoxia causes a temporary suppression of breathing due to withdrawal of peripheral chemoreceptor drive. After a few minutes of hyperoxia, ventilation increases to greater than control levels probably because of hyperoxic cerebral vasoconstriction resulting in increased brain tissue carbon dioxide. Immaturity and prolonged exposure to supplementary oxygen reduce the response to hyperoxia. The fetus and newborn respond to increased carbon dioxide levels with an increase in breathing activity. The slope of ventilatory response to carbon dioxide is less in term infants during active than quiet sleep, but it increases with postnatal growth. Other chemoreceptors include subepithelial chemoreceptors in the trachea, bronchi, and bronchioles that respond by changing the frequency and depth of respiration after exposure to toxic gases such as nitrogen dioxide and sulfur dioxide. This response is decreased during active sleep and in the premature infant.[59]

Respiratory activity is also regulated by nonchemical means, such as stimulation by the many respiratory reflexes.[51] Hering and Breuer described three respiratory reflexes: inflation, expiratory, and deflation. The Hering-Breuer inflation reflex is stimulated by lung inflation and results in cessation of respiratory activity. In the newborn the reflex produces a pattern of rapid, shallow tidal breathing and operates within the tidal volume range. In older subjects the reflex prevents excessive tidal volumes and can only be stimulated if the inflating volume is increased greater than a critical threshold.[60] The Hering-Breuer expiratory reflex is stimulated if inflation is prolonged; the active expiration seen in infants ventilated at slow rates and long inflation times, and which may result in pneumothoraces, may be a manifestation of this reflex.[61] In animal models the Hering-Breuer deflation reflex is evidenced by a prolonged inspiration generated in response to deflating the lung rapidly or following an unusually vigorous expiratory effort that takes the lung below its end-expiratory level.[62] In the newborn, this reflex may have a role in maintaining the FRC. Head's paradoxical reflex, also called the inspiratory augmenting reflex or provoked augmented inspiration, is the underlying mechanism of the first breath and sighing. A rapid inflation stimulates a stronger diaphragmatic contraction. The reflex improves compliance and reopens partially collapsed airways[63]; it has an important role in promoting lung expansion during resuscitation. Rapid chest wall distortion via the intercostal phrenic inhibitory reflex results in a shortening of inspiratory efforts. This reflex response is inhibited by an increase in FRC or applying CPAP. The mechanism may improve chest wall stability.[64] The airway is protected from bronchospasm induced by cold exposure by upper airway reflexes that can increase upper airway resistance and decrease inspiratory air flow. The laryngeal afferents defend the lower airway from inadvertent inhalation of foreign bodies, with maturation of the laryngeal reflex being characterized by an increase in coughing and a decrease in swallowing and apnea.[65] For a discussion of ventilatory control in sleep-disordered breathing, please refer to

Chapter 81.

## Apnea

Apnea is defined as cessation of breathing for at least 20 seconds or at least 10 seconds if associated with oxygen desaturation or bradycardia.[54] Apneas are classified as central, obstructive, or mixed.[66] Most apneas are central in nature (46%–69%), with the rest being either purely obstructive (6%–12%) or a combination of central and obstructive (i.e., mixed) (20%–44%).[67] Central apnea is characterized by cessation of inspiratory efforts in the absence of upper airway obstruction. In contrast, in obstructive apnea, despite the presence of central signals for breathing and the corresponding respiratory muscle activities, there is an absence of airflow through the airways due to upper airway obstruction. Bradycardia may occur within a few seconds of onset of apnea with accompanying disturbances in blood pressure and cerebral blood flow velocity. In infants without adequate cerebrovascular autoregulation, cerebral perfusion may decrease to very low levels during prolonged apnea and potentially exacerbate hypoxic-ischemic brain injury. The incidence of apnea of prematurity is inversely associated with GA and usually resolves by approximately 37–40 weeks postconceptional age.

Frequent episodes of apnea that respond to gentle stimulation may be considered normal for preterm infants. However, additional investigations and treatment are required if the apneas become frequent and/or associated with prolonged desaturation, because there are several potentially treatable associated factors that may be present (e.g., infection, intracranial abnormality or hemorrhage, anemia, metabolic disorders [e.g., hypoglycemia], temperature instability, and gastroesophageal reflux [GER] [see later in the chapter]). In addition, several pharmacologic agents (e.g., benzodiazepines and opioid analgesics) can also cause apnea. After excluding other treatable conditions, neonatal apnea may be treated with methylxanthines (e.g., theophylline) and caffeine, which have all been shown to reduce apnea in preterm infants, possibly by increasing the chemoreceptor sensitivity to carbon dioxide.[68] Caffeine is the preferred agent in view of its relatively long half-life, which allows once-daily dosing, and its higher therapeutic index compared with theophylline. Side effects of theophylline include hyperactivity, tachycardia, cardiac dysrhythmias, feeding intolerance, and seizures. Caffeine treatment in infants with, or at risk for, apnea of prematurity has also been shown to reduce BPD[69] and improve survival without neurodevelopmental delay.[70] In addition, prophylactic caffeine reduces apnea/bradycardia and episodes of oxygen desaturation in preterm infants following postoperative anesthesia.[71] Doxapram, a respiratory stimulant that is thought to act via the peripheral chemoreceptors, has been used to treat apnea in newborns but has been associated with many side effects (e.g., elevated blood pressure, abdominal distension, irritability, increased gastric residuals, and emesis). Furthermore, the long-term effects of this drug have not been adequately investigated.[68] Relatively novel treatments include olfactory stimulation,[72] inhalation of low-dose carbon dioxide,[73] and limb proprioception stimulation.[74] However, although some of these treatments show initial promise, whether they can be replicated in a wide variety of clinical situations and show any long-term advantages remain to be seen. Noninvasive ventilatory support (e.g., CPAP, noninvasive positive-pressure ventilation [NIPPV], and high-/low-flow nasal cannulas) may be considered for infants with frequent or prolonged apnea despite treatment with caffeine. The frequency of apnea has been shown to be decreased by increasing the FRC, stabilizing oxygenation, or by splinting the upper airway. Positive pressure support of the airway may be particularly effective in infants whose episodes are precipitated or prolonged by relative upper airway obstruction as both the pharynx and laryngeal aperture could be distended to reduce the risk of mixed and obstructive apneas. However, a neural component to the effects of positive pressure/flow has been suggested as even delivery of low-flow air has been shown to be effective, suggesting the possibility of the stabilization of the mechanoreceptors in the upper airway by the airflow.[68] Infants with severe and refractory apnea unresponsive to the relatively noninvasive modalities of treatment would need to be intubated and supported by mechanical ventilation.

## Periodic Breathing

Periodic breathing is a common breathing pattern that, unlike apnea of prematurity, can occur in infants of all GA.[75,76] In contrast to apnea of prematurity, periodic breathing does not usually occur within the first 48 hours of life[75] and can last for 6 months or longer.[76,77] The literature suggests that among healthy term babies, 78% exhibit periodic breathing within the first 2 weeks of life, decreasing to 29% by 1 year of age.[76] The definition of periodic breathing can be arbitrarily defined as three episodes of apnea of more than 3-second duration each that are interrupted by periods of breathing that are 20 seconds or less.[78] The etiology of periodic breathing is thought to be increased sensitivity of chemoreceptors involved in ventilatory control, leading to overregulation of the breathing pattern in response to small changes in $PaO_2$ or $PaCO_2$ levels.[79] This overcompensation leads to periodic overshooting of the target to be compensated for and the oscillation between apnea and normal breathing that is observed in this condition. Periodic breathing has previously been thought to be a benign condition. However, with improvements in computing power, detailed longitudinal analyses of neonatal breathing patterns have been made, and showed that preterm infants often exhibit increased percentage of time spent in periodic breathing before a diagnosis of necrotizing enterocolitis (NEC) or septicemia is made.[79] Furthermore, in another longitudinal study of preterm infants, it has been found that periodic breathing can be associated with significant desaturations and reduction in cerebral oxygenation, especially during sleep.[80] Although the use of CPAP or caffeine may be associated with less periodic breathing,[79] because the long-term clinical implications of these events are unknown, further follow-up studies are warranted before evidence-based diagnostic or treatment recommendations can be made.

# Respiratory Distress Syndrome

Respiratory distress syndrome (RDS), also referred to as hyaline membrane disease, is a respiratory condition that occurs in many preterm infants at birth and is defined by clinical and radiographic descriptions. Infants with RDS develop oxygen requirements within 6 hours of life, typically require respiratory support at 24 hours of life, and a have a chest x-ray with findings consistent with RDS.[81] The severity of RDS has decreased with the introduction of surfactant and antenatal steroids, so the classic hyaline membranes, seen at autopsy, rarely occur in our current premature infants.[82] Because many infants are ventilated in the delivery room and given surfactant, the radiologic evidence of air bronchograms may not be present. And some infants will be maintained on mechanical ventilation due to immature respiratory drive, yet have mature lungs with plenty of surfactant. Because it is difficult to define RDS in the era of surfactant therapy and antenatal steroids, there will be variations in the number of preterm infants with RDS across studies.[82] Some may argue the alternative name for RDS may have changed from "hyaline membrane disease" to "respiratory instability of prematurity," a phrase created by Bancalari and Jobs to describe the extremely preterm infants born in recent years.[82]

## Epidemiology

It is difficult to determine the exact incidence of RDS because multiple definitions exist. The incidence of RDS decreases as the GA increases. Prior to the introduction of antenatal steroids (1983–86), the incidence of RDS was: >95% at 25 weeks GA (average weight 800 g); 75% at 28 weeks (average weight 1000 g); 50% at 30 weeks GA (average weight 1400 g); and still approximately 20% at 34 weeks GA.[83] Antenatal steroids have been shown to reduce RDS by an average of 40% in randomized trials.[84] In the 1990s, when the more routine use of antenatal steroids was beginning (ACOG recommended steroid use in 1994), the incidence of RDS was approximately 70% between 500 and 1500 g.[85] Of note, in the Vermont Oxford network, the antenatal steroid rate increased from 23% in 1991 to 72% in 1999, but there was no difference in the rate of RDS.[85] Between 1997 and 2003, in the era of moderately high antenatal steroid use, approximately 63% of infants between 500 and 1000 g have RDS.[86] Although antenatal corticosteroids have traditionally been given to mothers at risk of preterm birth prior to 34 weeks GA, a randomized trial demonstrated a benefit of corticosteroids in late preterm infants.[87] The rates of RDS vary between races and sex. Female infants have a lower incidence of RDS than do male infants at all GAs,[88] which is consistent across most mammalian species. Late preterm males have an odds ratio (OR) of 1.68 of having RDS compared with their female counterparts.[89] Race plays an important role in the development of RDS, with African-American infants having a lower rate than do white infants.[90] In one study, only 40% of African infants less than 32 weeks GA developed RDS compared with 75% of the white infants.[91] Genetic variability as a risk factor for RDS has been confirmed in twin studies, in which monozygotic twins were more likely than dizygotic twins to both have RDS.[92,93] The largest influences on development of RDS are GA, gender, race, and antenatal steroids. Genetic polymorphisms of surfactant proteins have been found to be strongly associated with risk of RDS in preterm infants (see Chapter 57).[94]

## Pathophysiology

RDS is due to structural immaturity of the preterm lung and a deficiency in surfactant pool size. Increased lung fluid, inadequate respiratory efforts, and underdevelopment of the chest wall and respiratory muscles also contribute to the infant's inability to maintain expansion of the distal airspaces. Surfactant production and maturation are covered in detail in Chapter 5, so only a summary will follow. Surfactant is produced in alveolar type II cells, which are cuboidal cells covering approximately 2% of the alveolar surface that become more prominent between 22 and 24 weeks GA. Surfactant is a complex mixture of phospholipids, neutral lipids, and proteins (surfactant proteins A, B, C, and D). Lipids make up more than 90% of surfactant, with 80% being phospholipids (phosphatidylcholine [PC] and phosphatidylglycerol [PG] make up largest portion) and 10% neutral lipids (cholesterol, triacylglycerol, and free fatty acids).[95] Sphingomyelin, which is used in the lecithin to sphingomyelin (L:S) ratio, represents less than 2% of surfactant lipid. Surfactant is synthesized in the endoplasmic reticulum, collected in the lamellar bodies then released into airspace as active tubular myelin. The tubular myelin mixes with a combination of saturated and unsaturated phospholipids to make a surface film that decreases surface tension. The surface film is recycled over time by the type II cells or degraded by the macrophages. More than 90% of the PC on the alveolar surface is reprocessed, the turnover time being approximately 10 hours. The phospholipid monolayer structure allows the surfactant to change shape throughout respiration, with the most distended form allowing decreased surface tension and the most compressed form in exhalation providing stability to the alveoli. In RDS the immature lung has a lower level of PG and PC, the spreading agents for surfactant in the lung, thus the monolayer formed is unstable and does not decrease surface tension or maintain alveolar patency as well. The immature surfactant system in preterm infants with RDS leads to difficulty in generating an FRC and increased work of breathing. The addition of PEEP or treatment with exogenous surfactant allows for formation of an FRC and decreased injury from ventilation.[19,96] In RDS the resultant alveolar hypoventilation results in ventilation perfusion imbalance and hypoxia. The increased alveolar surface tension from the surfactant deficiency promotes the flow of protein-rich fluid from the intravascular space to the alveolar spaces. The leak of protein is increased by mechanical ventilation and from continued hypoxic damage to the alveolar-capillary membrane. These plasma proteins further inhibit surfactant function and make up a major component of the hyaline membrane found in infants who do not survive RDS.

The four surfactant-associated proteins, SP-A, SP-B, SP-C, and SP-D, compose approximately 10% of surfactant and play a role in the structure of tubular myelin (SP-A), the stabilization of the phospholipid monolayer (SP-B, SP-C), and in host-defense (SP-A, SP-D). ABCA3 is a protein that assists in transport of lipids with type II cells and is required for proper lamellar body formation. Genetic mutations in the surfactant proteins or ABCA3 lead to respiratory disease in the newborn that ranges from mild (SP-A) to lethal (SP-B).[97] Some of the clinical manifestations of these conditions do not appear until childhood or adulthood. The role of gene mutations in human lung diseases and surfactant production are covered in depth in Chapters 5 and 57. Term or late preterm infants with severe RDS at birth that does not have a persistent response to surfactant therapy may need to be evaluated for these mutations.

Many factors influence lung maturation and surfactant production and thus the development of RDS. Both fetal cortisol and thyroxine can stimulate lung maturation. Conversely, insulin delays the maturation of alveolar type II cells, decreasing the proportion of saturated PC, and inhibits the production of SP-A and SP-B.[98] Infants of diabetic mothers also have delayed appearance of PG, and the infant's L:S ratio is less predictive of lung maturation.[99] The increased incidence of RDS in males (1.7 : 1) may be due to the increased levels of fetal androgens. Fetal androgens delay lung maturation and PG production (by approximately a week) through direct action on lung fibroblasts.[100] Any factors that affect the integrity of the alveolar capillary membrane (asphyxia, hypothermia, or hypoxia) will lead to increased airspace protein and deactivation of surfactant function. Although often necessary in the resuscitation of preterm infants, PPV can release proteins and cause inflammation that worsens RDS.[101,102] Increased intrauterine inflammation from chorioamnionitis matures the lung and decreases the risk of RDS but may increase the risk of BPD.[103,104]

## Clinical Presentation

Infants with RDS typically present within 4 hours of birth with tachypnea (respiratory rate > 60 breaths/min), intercostal and subcostal retraction, nasal flaring, and abdominal breathing. Although severe cases of RDS present with cyanosis, milder cases of RDS are discovered by routine use of pulse oximetry in infants unable to maintain their saturations greater than 90 on RA. The high surface tension in the alveoli created by the surfactant deficiency and the weaker chest wall muscles of the preterm infant may make it difficult for the infant to develop the normal FRC of 25–30 mL/kg, and thus the infant's lungs remain in a partially deflated state. The infant may attempt to increase their FRC through an expiratory grunt, created when the infant simultaneously contracts the diaphragm and the constrictor muscles of the larynx to close the upper airway. The resultant exhalation of air is exaggerated and creates the grunting sound found in RDS. The diffuse collapse of the alveoli and smaller airways creates the classic chest radiograph findings of ground-glass appearance with air bronchograms. In infants who are not treated with exogenous surfactant, the symptoms worsen over the first 24–36 hours due to collapse of alveoli recruited by the initial breaths at birth and the deactivation of the small amounts of surfactant present in an infant with RDS. The ongoing lung injury from atelectasis and poor ventilation leads to further leak of inhibitory plasma proteins into the airspace, a cycle that can be prevented by the treatment with exogenous surfactant or CPAP.[105] Without antenatal steroids, endogenous levels of surfactant begin to increase in the airspaces by 24 hours after birth.[106] Between 36 and 48 hours of age, the endogenous production of surfactant is sufficient to maintain alveolar patency and clinical symptoms improve. Often this process is associated with a spontaneous diuresis. With eventual development of surfactant production, recovery from RDS with decreasing oxygen requirements normally occurs by approximately 1 week of age. Extremely preterm infants often require ongoing ventilator support due to chest wall weakness and central respiratory drive issues. The introduction of exogenous surfactant treatment and antenatal steroids has altered the traditional clinical progression over a course of days because most larger infants with significant respiratory distress will receive surfactant and this will be recycled by their type II cells multiple times prior to their own endogenous production.

## Diagnosis and Differential Diagnosis

The diagnosis of RDS is made on clinical history (described previously) and chest radiographic appearance. The chest radiograph shows fine granular opacification in both lung fields due to diffuse atelectasis and air bronchograms, where the air-filled bronchi stand out against the atelectatic lungs (Fig. 19.2). In severe cases the lungs are collapsed to the extent that the cardiac silhouette is indistinguishable from the lungs. If the radiograph is taken during the first 4 hours, the retention of fetal lung fluid can make interpretation difficult. As the fluid clears, the chest radiograph appearance may show marked improvement. It should be noted that an infant on mechanical ventilation with adequate tidal volume ventilation and PEEP will have a moderately clear x-ray, even in the setting of significant surfactant deficiency. This difference can be determined clinically because the infants with surfactant deficiency will require higher pressures to maintain tidal volumes. Preterm infants with low lung compliance (i.e., requiring peak inspiratory pressure [PIP] greater than approximately 20 cm $H_2O$ to generate a tidal volume of 5 mL/kg) would benefit from exogenous surfactant therapy. Although measurement of surfactant in a tracheal aspirate can be performed, this is currently not clinically available.[107] Tracheal secretions or gastric contents can be aspirated and a bubble shake test can be performed to give a basic assessment of surfactant levels, but this is rarely done in the NICU.[108]

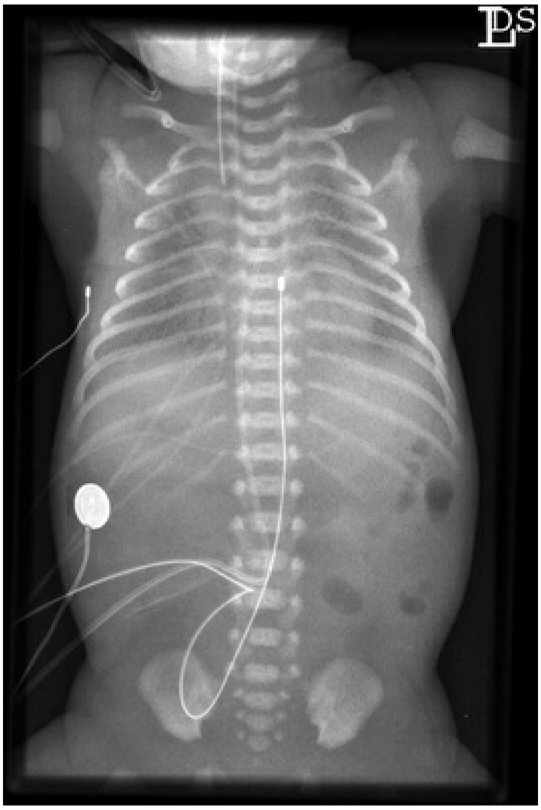

**FIG. 19.2** Respiratory distress syndrome: chest x-ray demonstrates ground-glass appearance and air bronchograms due to atelectasis because of surfactant deficiency from prematurity.

Fetal lung fluid normally moves up the trachea and is swallowed by the fetus, but some of the fluid mixes with the amniotic fluid, allowing surfactant to be measured. As the lung matures, the amount of dipalmitoylphosphatidylcholine (DPPC) in the amniotic fluid increases, but the amount of sphingomyelin remains unchanged throughout gestation; thus lung maturity can be assessed from the L:S ratio.[109] The lower the L:S ratio, the more likely that the infant will develop RDS: 80% of infants with a L:S ratio < 1.5 have RDS, compared with 21% of infants with a ratio of 1.5–2.0, and approximately 5% if L:S ratio > 2.0 (usually is associated with lung maturity).[109] Because of the abnormalities in PG formation (not measured in L:S ratio) in infants of diabetic mothers and infants with severe hemolytic disease, these infants may have a mature L:S ratio but have significant RDS.[99] L:S ratios can be altered by the presence of blood, meconium, or vaginal secretions in the sample. Lung maturity can also be assessed by the lamellar body count in the amniotic fluid.[109,110] Lamellar body counts are more sensitive than L:S ratio and >37,000 correlates well with lung maturity, even in diabetic patients (30,000 in nondiabetic women).[109,111] Lamellar body counts can be easily obtained by running amniotic fluid through an automated hematology analyzer because they are the same size as platelets. Some investigators suggest that examining lamellar body counts in gastric aspirates of preterm infants may be helpful to guide the early use of surfactant.[112]

It is nearly impossible to differentiate severe early-onset sepsis or pneumonia from RDS, either clinically or radiographically. Because these conditions can also coexist, infants experiencing respiratory distress at birth should have an appropriate workup performed for bacterial infections (blood cultures, complete blood count [CBC], and C-reactive protein at >4 hours) and should then be started on antibiotics.[113] Clinicians may consider holding antibiotics in the setting of preterm delivery for maternal reasons (preeclampsia, Hemolysis, Elevated Liver enzymes, and Low Platelet count [HELLP] syndrome). Antibiotics should be stopped after blood cultures and other lab results are negative. Ampicillin and gentamicin act synergistically against group B streptococcus (GBS) and are also effective against many organisms that cause early-onset septicemia and pneumonia. It is important to know the local antibiotic resistance patterns as gentamicin resistant gram-negative bacteria have become more prevalent. Infants with high oxygen requirements, but a clear chest x-ray or low lung compliance, may be suffering from pulmonary hypertension. This can often be diagnosed with preductal and postductal pulse-oximetry or echocardiography and can be treated with sedation and inhaled nitric oxide (iNO). TTN (discussed later) can present with similar findings to RDS but typically improves more quickly as the excessive water in the lungs is absorbed and the function of the (already present) surfactant improves. Respiratory distress that presents after 4–6 hours of age is usually due to pneumonia; the differential diagnosis includes air leak, heart failure secondary to congenital heart disease, and aspiration.

## Management

The appropriate management of preterm infants with RDS has been studied extensively over the past decade, yet there is not a clear consensus among neonatologists about the best approach to take in the delivery room. Everyone would probably agree that RDS is due to a combination of chest wall immaturity and surfactant deficiency and that all treatment methods are merely approaches to bridge the time until the infant begins to develop sufficient endogenous surfactant (typically over 48 hours) and grows stronger to maintain adequate respiration (days to weeks). The three typical management styles for RDS (described in detail later) all derive from these principles: (1) use of CPAP to maintain alveolar distention during spontaneous breathing,[34,35] (2) giving exogenous surfactant while the infant is spontaneously breathing (minimally invasive surfactant therapy [MIST] or less invasive surfactant therapy [LIST]),[114,115] or (3) mechanical ventilation and administration of surfactant therapy, with rapid extubation as part of INSURE (Intubation, Surfactant, Rapid Extubation) protocols.[33,116] Other forms of noninvasive respiratory support (high-flow nasal cannula and NIPPV) have also been tried for RDS.

Since its introduction in the early 1990s, exogenous surfactant therapy has had a dramatic effect on the survival and long-term morbidity from RDS. The first description of surfactant deficiency was published by Avery in 1959,[117] but it took nearly 30 years to get an animal-extracted surfactant approved for clinical use in premature infants. Surfactant therapy, when given as "rescue therapy" in infants with established RDS, decreased the rates of pneumothorax, mortality, and the combined outcome of mortality and BPD.[118] Surfactant therapy has also been shown to be more effective if given as "prophylactic therapy" to infants born less than 28 weeks gestation versus given as rescue therapy, with decreased risk of pneumothorax, pulmonary interstitial emphysema (PIE), and mortality or BPD.[33] It should be noted that the majority of the surfactant therapeutic trials were conducted prior to the ACOG recommendation for antenatal steroid use in 1994 and the infants included in the studies may be slightly less mature than extremely preterm infants who have received steroids.[119] The benefit of prophylactic surfactant in the setting of antenatal steroids has been addressed by multiple trials of surfactant versus CPAP (discussed later).[120] Most intubated extremely preterm infants, even in the setting of intubation for respiratory drive or apnea, would benefit from surfactant therapy because mechanical ventilation alone may release proteins that inhibit the endogenous surfactant.[107] Benefits are shown after a single dose of 100 mg/kg surfactant, but most studies demonstrate that better results are obtained with more than one dose.[121] The results of additional surfactant begin to diminish after the second dose of natural surfactants. There may be differences between bovine surfactant (beractant) and porcine surfactant (poractant alfa), with further benefits on BPD, mortality, and patent ductus arteriosus (PDA) seen with poractant. These differences between surfactants may be due to the higher dosing concentrations given with poractant (200 mg/kg) versus the beractant (100 mg/kg).[122] Natural (animal-derived) surfactants when compared with synthetic surfactant (protein free) are associated with a significant reduction in mortality and pneumothorax but may be associated with an increased risk of NEC.[123] The most well-studied protein-free surfactant, colfosceril palmitate (Exosurf), is no longer being produced. Synthetic surfactants are now available that contain synthetic polypeptide proteins designed to mimic surfactant proteins B or C. The most studied polypeptide is KL4, designed to mimic the C-terminal end of surfactant protein B,[124] which when mixed with DPPC, POPG phospholipids, and palmitic acid is called lucinactant (Surfaxin). KL4 appears to be more resistant to the inhibitory effects of proteins than natural surfactants.[125] Transient hypoxemia and bradycardia may be present during surfactant treatment via ET tube. A transient perturbation in cerebral hemodynamics is also present but is not associated with increased risk of cerebral hemorrhage. Pulmonary hemorrhage has been noted following surfactant administration. Surfactant, once instilled into the trachea or bronchus, will quickly spread throughout the lungs with each breath. Although surfactant dosing is approved for four quadrants, most clinicians instill surfactant with only two positions. In some surfactant-deficient preterm infants, the ET tube serves mainly as a conduit for administering surfactant, but intubation may expose the infant to injurious ventilation and cardiovascular changes. To avoid continued ventilation after surfactant treatment, the INSURE technique has been adopted by many neonatologists, especially for more mature infants (>28 weeks GA) in need of surfactant treatment.[126] To avoid intubation in spontaneously breathing infants on CPAP with higher oxygen needs, surfactant can be given through a thin catheter into the trachea of extremely preterm infants.[114,115] MIST or LIST involve direct visualization of the vocal cords by direct laryngoscopy and insertion of a feeding tube into the upper trachea (www.youtube.com/watch?v=OUvgJ57FQR8). Surfactant is then quickly instilled through the feeding tube. MIST therapy has been shown to be effective and may avoid unnecessary mechanical ventilation in preterm infants.[127] Surfactant can also be given through a laryngeal mask airway (LMA), but LMAs small enough for extremely preterm infants are still in development. Nebulization of surfactant in spontaneously breathing infants on CPAP is being studied in clinical trials. It is known that some extremely preterm infants are surfactant deficient and need surfactant treatment, but the best way to deliver it is still being determined.

Not all infants with clinical signs of RDS are surfactant deficient, especially in the setting of greater than 48 hours of antenatal steroids, and many of these infants require only CPAP to support the weak respiratory muscles and to stimulate breathing.[35,128] The mildest forms of RDS can sometimes be managed with supplemental oxygen, but most babies need some form of distending pressure to prevent atelectasis and improve oxygenation. Many centers are trialing all infants on CPAP in the delivery room, and approximately 50% of infants born less than 750 g can be maintained on only CPAP, with much higher rates in more mature infants.[36,37,129] The ability to be maintained on CPAP is likely due to the small amount of endogenous surfactant (>5% of term surfactant pool size needed in preterm sheep) necessary to maintain alveolar expansion.[38] Over the past decade, during an era of greater than 80% antenatal steroid rates, five major trials (Continuous Positive Airway Pressure or Intubation at Birth trial [COIN]; Surfactant, Positive Pressure, and Oxygenation Randomized Trial [SUPPORT]; Vermont-Oxford Network [VON] delivery room study; an international randomized controlled trial to evaluate the efficacy of combining prophylactic surfactant and early nasal continuous positive airway pressure in very preterm infants [CUPAP]; and Neocosur Network) have been conducted to compare CPAP versus intubation and surfactant in extremely preterm infants less than 29 weeks. Even with the use of early CPAP in the delivery room, the decrease in the incidence of BPD is modest at approximately 10%.[36,129] The increased rate of pneumothorax found in the COIN trial was not found in any of the other clinical trials, with an overall pneumothorax rate in all trials of CPAP 6.3% versus surfactant 5.8%. Based on these studies, the 2015 ILCOR resuscitation guidelines recommend treating spontaneously breathing preterm infants (<30 weeks) with CPAP instead of intubation.[5] Preterm infants started on CPAP may initially do well ($FiO_2$ less than 30%), and then having increasing oxygen requirements and hypercapnia as alveoli begin to collapse. Although $PcCO_2 > 60$ mm Hg and a $FiO_2 > 0.6$ is used by some centers as criteria for CPAP failure (including some centers with very low BPD rates), 84% of preterm infants on CPAP with a $FiO_2$ of >0.4 will reach >0.6.[130] Earlier rescue surfactant, given when $FiO_2 < 0.45$, has been shown to be beneficial for air leaks,[126] and it is our practice to intubate these infants and give them surfactant if they require $FiO_2 > 0.4$ on high levels of CPAP. Increasing the level of CPAP increases the lung volume and hence improves oxygenation, but it is possible to cause overdistension, carbon dioxide retention, and air leaks. CPAP can be generated by a mechanical ventilator, a T-piece resuscitator, or an underwater seal (bubble) device (bubble continuous positive airway pressure [BCPAP]). BCPAP is attractive, especially for low-resource countries, because the CPAP is regulated by submerging the expiratory limb of the gas circuit a set distance under water (actual cm $H_2O$). It should be noted that the distending pressure generated by BCPAP is flow dependent and intraprong pressures may be higher (up to 1.3 cm $H_2O$) than expected for the depth of submersion in water.[131] Unlike ventilator-derived CPAP, BCPAP generates a variable distending pressure, often referred to as the "noise" of BCPAP.[132] In intubated sheep, BCPAP had improved gas exchange, oxygenation, and pH compared with ventilator-derived CPAP,[132] and similar benefit was seen on oxygenation in preterm infants on BCPAP.[133] When the pressure fluctuations are further increased (high-amplitude BCPAP), the oscillatory pressure wave can achieve similar blood gas values in paralyzed, saline-lavaged rabbits to conventional mechanical ventilation.[134] The transmission of the oscillatory bubbles and the CPAP pressure may differ based on the nasal interface used, with the RAM cannula losing more CPAP pressure than other nasal-prong interfaces. Heated humidified high-flow nasal cannula (HHHFNC) is used by some units to treat RDS and has been shown not to be "inferior" to CPAP in clinical trials.[135] The variability of pressures generated in preterm infants on HHHFNC, often caused by leaks through the mouth, makes it a less predictable form of distending pressure.

Preterm infants may need PPV due to poor respiratory drive (apnea of prematurity), inability to maintain chest expansion on CPAP (surfactant deficiency, respiratory muscle weakness), or ineffective gas exchange (hypoxia or hypercarbia). PPV can be given via an ET tube (traditional mechanical ventilation) or through nasal prongs (NIPPV). In meta-analysis of studies comparing NIPPV with CPAP following extubation, NIPPV reduced the incidence of extubation failure but had no effect on BPD or mortality.[136] Although earlier studies demonstrated a benefit of synchronized NIPPV on BPD, more recent, larger studies, which used unsynchronized NIPPV with lower average PIPs, found no difference.[137] In unsynchronized NIPPV, only 25% of breaths were coordinated with infant's breaths and only these breaths led to an increase tidal volume. The ability to synchronize breaths can now be done with neurally adjusted ventilatory assist (NAVA), which uses an esophageal catheter to measure diaphragmatic electrical activity to both synchronize breaths and adjust ventilator pressures. NAVA has been shown to decrease BPD in some small studies[138] but needs to be studied in a randomized trial for prevention of BPD. Conventional mechanical ventilators deliver intermittent positive-pressure inflations and PEEP at a preset rate and inspiratory time. The ventilator inflations are often not synchronized with the infant's breaths, and this can contribute to air leak syndromes. Many neonatologists now use higher rates and lower tidal volumes to improve asynchrony and decrease possible lung injury from alveolar overdistention. Volutrauma, from high tidal volumes, and atelectrauma, from inadequate stenting of the airways with PEEP at the end of expiration, are likely more dangerous to the developing lung than the pressures used to generate these volumes. The development of infant mechanical ventilators with accurate flow sensors at the end of the ET tube has allowed for the more reliable use of volume ventilation in the NICU. Studies comparing volume to pressure ventilation in preterm infants demonstrate a benefit for volume ventilation of reduced death or BPD, duration of ventilation, pneumothoraces, periventricular leukomalacia, and severe intraventricular hemorrhage.[139] Volume ventilation also allows for rapid changes in inspiratory pressures in response to changes in lung compliance, especially in the setting of exogenous surfactant administration or use of postnatal corticosteroids. An alternative approach to conventional mechanical ventilation, which generates a tidal volume of 4–6 mL/kg through either pressure or volume control, is to use extremely small volumes but very high rates. During high-frequency jet ventilation (HFJV), high-velocity bursts of gas are fired at rates of 200–600 per minute to generate gas flow down the ET tube. There are few randomized trials comparing HFJV with conventional ventilation, but the largest included approximately 130 infants and demonstrated a slight decrease in BPD rates and need for home oxygen.[140] High-frequency oscillatory ventilation (HFOV) uses a piston to generate a gas gradient within the dead space of the trachea, with gas exchange reliant on oxygen moving down the gradient into the lungs and carbon dioxide diffusing along its gradient out of the lung. Because HFOV relies on forming oxygen and carbon dioxide gradients, extremely active infants or those breathing against the ventilator may affect the gas exchange ability of the ventilator. Randomized trials comparing HFOV to conventional ventilation have variable results, but a meta-analysis demonstrated that HFOV is associated with a modest reduction in BPD, with no excess of intraventricular hemorrhage (IVH) or periventricular leukomalacia (PVL).[141] Surprisingly, especially because many clinicians use HFOV in setting of PIE, HFOV was also associated with a mild increase in air leaks.[141] Use of open lung strategies with HFOV, where mean airway pressure (MAP) is increased until there is no longer an improvement in oxygenation and then decreased by 2 cm $H_2O$, may lead to improved pulmonary responses in preterm infants. Infants with RDS whose hypoxia is more severe than would be anticipated from the chest radiograph, and who have low lung compliance, should be evaluated for pulmonary hypertension.

## Preventative Strategies

Antenatal steroids (dexamethasone or betamethasone) can cross the placenta to mature the fetal lung and brain.[142] In the lung, antenatal steroids can decrease the fetal lung fluid through activation of ENaCs, induce the production of surfactant proteins and lipid synthesis, and alter preterm responses to oxidative stress.[142,143] Randomized trials have demonstrated that administration of antenatal corticosteroids significantly reduces the incidences of RDS, neonatal death, cerebral hemorrhage, and NEC.[84] Guidelines recommend the routine use of antenatal steroids for mothers at risk for preterm delivery from 24 weeks to 34 weeks GA.[144] Betamethasone (two doses 24 hours apart), rather than dexamethasone (four doses 12 hours apart), is preferred. Antenatal steroids can be considered at 23 weeks GA but are not currently recommended at 22 weeks GA.[144] Studies have also demonstrated decreased respiratory complications in late preterm infants (34–36 weeks) randomized to antenatal corticosteroids, and revisions to

ACOG guidelines are underway.[87,142] Studies of antenatal steroids prior to elective C-section also demonstrate some benefit on respiratory symptoms at birth.[145] The benefit of steroids is maximal in infants delivered between 24 and 168 hours after maternal therapy, but benefits on the lungs are seen in less than 24 hours.[119] The use of repetitive courses of antenatal steroids showed some benefits for respiratory outcomes, but more than five weekly courses caused decreased fetal growth and head circumference.[142] Infants who received repetitive dosing did not show differences in adverse neurologic outcomes at 18-month follow-up. Some obstetricians will give an additional dose of steroids to a mother with persistent threat of preterm delivery 1–2 weeks after initial course. Antenatal steroids do not increase the risk of infection in pregnancies complicated by preterm prelabor rupture of the membranes. There is not a consensus opinion about the use of antenatal steroids for infants of mothers with possible chorioamnionitis.

Thyroid hormones induce surfactant synthesis in animal models. Randomized trials of antenatal administration of thyrotropin-releasing hormone (the only component of the pathway that crosses the placenta) did not reduce the risk of neonatal respiratory distress or BPD, and unfortunately increased the risk of lower 5-minute Apgar scores and caused transient suppression of the pituitary system.[146] Other drugs such as aminophylline, ambroxol, and terbutaline have also been tried, with variable success.

## Mortality and Morbidity

Overall the mortality from RDS is 5%–10%; the mortality rate is inversely proportional to GA. The use of antenatal steroids and exogenous surfactant therapy has decreased the mortality from RDS, but significant morbidities still exist in the extremely preterm infants that survive. The acute complications of RDS include air leaks, PDA, and pulmonary hemorrhage (discussed separately later). BPD, defined as either oxygen dependency 28 days after birth or at 36 weeks corrected GA, develops in more than 40% of infants born prior to 29 weeks of gestation. BPD is discussed at length in Chapter 20. Some of these infants require tracheostomy and prolonged mechanical ventilation (see Chapter 21). Changes in antenatal steroid use, modes of respiratory support, and endogenous surfactant have fortunately created a very different form of RDS than was first described by Northway in 1967.

# Transient Tachypnea of the Newborn

## Epidemiology

Although the exact numbers are unclear, TTN occurs in less than 1% of term vaginal deliveries but is more frequent in late preterm infants.[87] Each week of GA after 35 weeks reduces the risk of respiratory symptoms, particularly if primary C-section is performed.[147] Other risk factors for TTN include C-section birth, with or without labor (threefold higher risk), male sex, macrosomia, maternal diabetes, and maternal history of asthma. Infants of asthmatic mothers may have a genetic predisposition to decreased responsiveness of β-adrenergic stimulation of ENaCs, increasing the risk of TTN and RDS.[148] Antenatal corticosteroids given to women at risk for preterm labor at 34–36 weeks decreased the risk of respiratory support and oxygen need.[87]

## Pathophysiology

This syndrome is thought to result directly from ineffective clearance of fetal lung fluid at the time of birth (see previous description of lung clearance). The lack of uterine contractions causing spinal flexion, and catecholamine surge from labor, lead to increased fetal lung fluid at birth and an increased risk of TTN with elective C-section.[1] The excessive fluid in the lung interacts with the surfactant, which is often at adequate levels to maintain alveolar expansion, and leads to relative inactivation of the surfactant until the fluid is absorbed. A subpopulation of term infants with TTN, often ones who have prolonged hypoxia and tachypnea, have a degree of surfactant deficiency that contributes to the respiratory distress.[149] Inadequate $Na^+$ transport out of the airways, either because of decreased numbers of ENaCs or lack of activation of these channels, contributes to the excess fluid.[14,150] The number of water channels (aquaporins) may also differ in infants with TTN.[15] Preterm infants also have decreased $Na^+$ transport, and late preterm infants with TTN have low amounts of surfactant.[151] The increased fluid accumulates in the interstitial space generating increased pressure and increased refilling of the airways with fluid during expiration, which can be overcome by CPAP in many infants.[1]

## Clinical Presentation

Infants with TTN are tachypneic with respiratory rates that can be greater than 80 breaths/min. The clinical presentation can resemble mild RDS, although the infants have grunting less often.[152] The chest may be barrel shaped because of hyperinflation. The chest radiograph shows hyperinflation, prominent perihilar vascular markings due to engorgement of the periarterial lymphatics, edema of the interlobar septae, and fluid in the fissures (Fig. 19.3). Some infants with TTN will develop pulmonary hypertension, and this should be suspected in infants requiring high concentrations of oxygen.

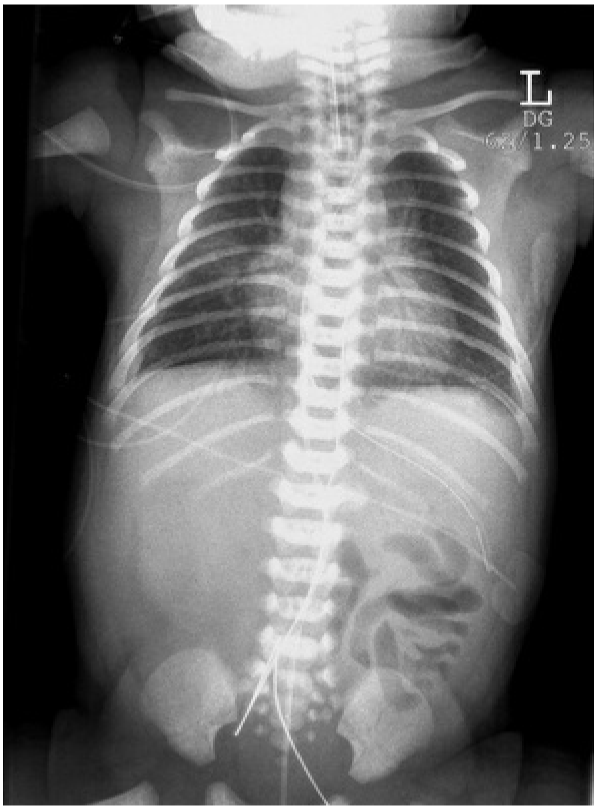

**FIG. 19.3** Transient tachypnea of the newborn: excess

lung fluid causes transient deactivation of surfactant and similar appearance to mild respiratory distress syndrome. Increased fluid is visible in fissures, with increased vascular markings in the lungs.

## Management

Most infants with TTN can be managed with supplemental oxygen or CPAP. CPAP will help to drive the excessive fluid out of airways and into the interstitial spaces, where it is absorbed over a few hours. Except in the setting of elective C-section or C-section for maternal reasons not related to infection, IV antimicrobials should be considered because sepsis and pneumonia in the term infant can mimic TTN clinically. TTN is usually self-limiting, and affected infants usually have significant clinical improvement within the first 24 hours and complete recovery within a few days of birth. Complications are rare, but air leaks may occur. Many infants with TTN have respiratory rates too high for safe oral feeding, so intravenous fluids or gavage feeds may be necessary until the tachypnea improves. Trials of furosemide or racemic epinephrine to increase fluid clearance have not shown clear benefits. More recently, it has been suggested that affected infants may derive clinical benefit from inhaled β-adrenergic agonist therapy[153,154]; however, larger trials are required.

# Meconium Aspiration Syndrome

## Epidemiology

Meconium-stained amniotic fluid (MSAF) complicates approximately 13% of live births,[155,156] affecting term more than preterm infants. MSAF occurs in less than 5% of preterm pregnancies, and when it does occur it suggests infection. Five percent of babies born through MSAF will develop meconium aspiration syndrome (MAS). In a large study of perinatal registry data in a developed setting, it was found that the overall incidence of MAS was 0.43/1000 live births. The incidence has been decreasing with time; it is associated with factors including advanced GA, low Apgar scores, and C-section delivery.[157] MAS is therefore a condition that predominantly affects term and postterm babies.

## Pathophysiology

MASF occurs when there is antenatal passage of meconium. This phenomenon has been associated with fetal distress and hypoxic-ischemic insult. MAS is an inflammatory lung condition caused by aspiration of MSAF by the infant into the airways during the peripartum period.

It has been found that antenatal passage of meconium is associated with higher levels of motilin in the baby.[158] Motilin is produced mainly by endocrine M cells of the duodenojejunal mucosa and stimulates peristalsis.[159] Levels are very low in preterm infants and nonasphyxiated term infants but are raised in asphyxiated term babies who pass meconium during the peripartum period. Prolonged severe fetal hypoxia can stimulate fetal gasping *in utero* leading to inhalation of MSAF. It is also thought that inhalation can occur perinatally with the first breaths of the baby who is delivered through MSAF. Although meconium is mainly made up of water (approximately 80%), it is chemically complex, containing components of various substances, including digestive juices, lipids, intestinal epithelial cells, lanugo hair, bile, and amniotic fluid.[160,161] It is of variable consistency and, when inhaled, can create a ball-valve mechanism within the airways. This obstructive pathology predisposes the lungs to air trapping and hyperinflation. In addition, meconium irritates the lungs, activating numerous inflammatory mediators, toll-like receptors, and the complement system.[161] An inflammatory pneumonitis and systemic inflammatory response can ensue, with an associated release of vasoactive substances that can cause vasoconstriction and raised pulmonary arterial pressure. In addition, meconium impairs surfactant function, increasing the possibility of atelectasis. Meconium harbors microbiota that are associated with amniotic fluid and placental microbiota.[162] In addition, meconium is thought to enhance bacterial growth by serving as a growth factor and inhibiting bacteriostatic properties of amniotic fluid,[163] facilitating the growth of pathogens such as *Escherichia coli.* Meconium has been suggested to significantly impair mechanisms of intracellular microbial killing, inhibiting phagocytosis and the neutrophil oxidative burst.

## Clinical Features

Infants with MAS generally present with signs of respiratory distress such as tachypnea and use of accessory muscles of respiration. The obstructive pathology can lead to increased anteroposterior diameter of the chest, whereas the ventilation-perfusion mismatch and pulmonary hypertension can lead to cyanosis. Initial chest radiographs may show hyperinflated lung fields and widespread patchy infiltrates (Fig. 19.4). Small pleural effusions occur in approximately 20% of patients. With development of pneumonitis and interstitial edema the radiographic appearance can progress to diffuse, homogeneous opacification of both lung fields. Air leaks, such as pneumothorax and pneumomediastinum, are very common, occurring in approximately 20% of infants. In those with pulmonary hypertension, right-to-left shunting at ductal and atrial levels may be seen by echocardiography. Differential diagnoses include pneumonia, surfactant deficiency, persistent pulmonary hypertension of the newborn (PPHN), congenital cardiac disease, and aspiration of blood.[164]

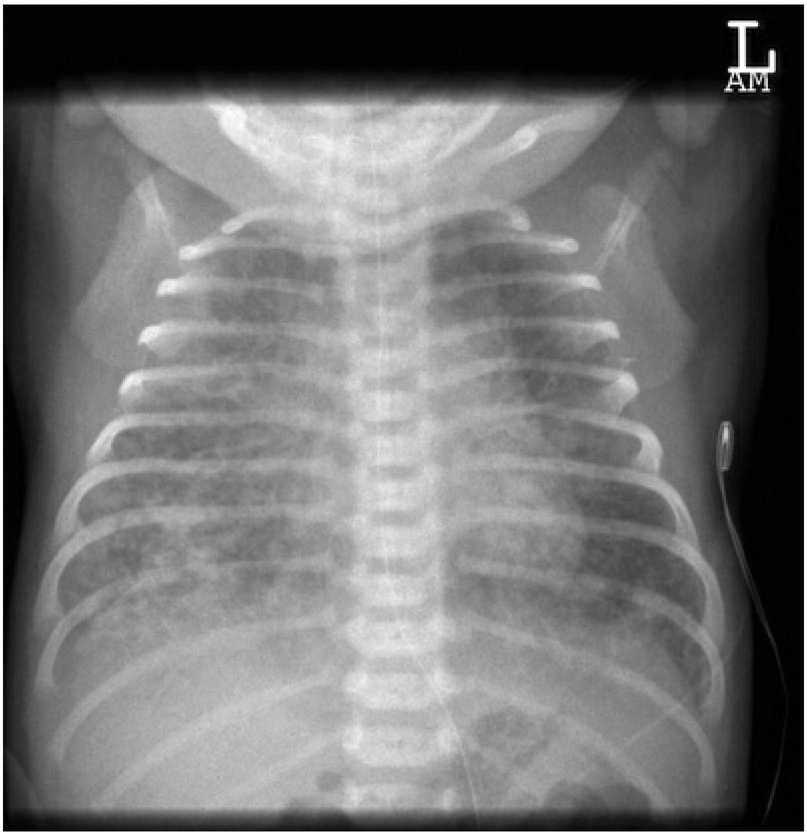

**FIG. 19.4** Meconium aspiration syndrome: chest x-ray with hyperinflation and patchy infiltrates throughout both lung fields.

## Management

Although infants mildly affected by MAS may require no specific treatment, a substantial proportion of infants will require intensive care management of the many complications that can arise. The risk of pulmonary hypertension is high in infants with MAS, and hypoxemia should be avoided. Supplemental oxygen should be administered to keep oxygen saturations greater than 94%. One should also consider using $PaO_2$ to guide oxygen use. With increasing evidence that high oxygen concentrations can cause harm, ventilatory support measures such as CPAP or mechanical ventilation should be considered if the $FiO_2$ requirement is persistently high. Traditionally MAS has been conceptualized as a primarily obstructive condition; however, it is now increasingly recognized that areas of hyperinflation may coexist with atelectasis in a setting of ventilation-perfusion mismatch.[164] It is therefore essential that ventilatory support should be initiated with close monitoring of the progress of the infant. Use of CPAP or mechanical ventilation may improve oxygenation but may also increase the risk of air leak. The thresholds at which ventilatory support should be initiated are therefore not evidence based and may need to be adjusted depending on the condition of the individual baby. In general, mechanical ventilation would be considered in infants with $PaCO_2 > 8$ kPa (>60 mm Hg) and $PaO_2 < 6$ kPa (<50 mm Hg) despite initial oxygen supplementation, especially in infants with evidence of PPHN. Conventionally, the ventilator strategy should be based on a relatively low PEEP and long expiratory time, but in practice, the appropriateness of this strategy will depend on the relative balance between atelectasis and hyperinflation. In infants with severe disease, and particularly if associated with pulmonary hypertension, HFOV and adjunctive use of inhaled NO should be considered.[165,166] In a meta-analysis that included four randomized trials, it was suggested that surfactant administration could reduce the severity of respiratory illness and decrease the number of infants with progressive respiratory failure requiring support with extracorporeal membrane oxygenation (ECMO),[167] especially if administered as a bolus. Surfactant administration both as lung lavage and as a bolus reduced duration of mechanical ventilation and length of hospital stay but did not reduce mortality.[168] The use of antibiotics has not been shown to benefit infants with MAS in terms of duration of ventilation, hospital stay, or mortality.[168,169] However, despite this, it is widespread practice to commence broad-spectrum antibiotics empirically in view of the difficulty in differentiating between MAS and pneumonia. Results of a randomized trial suggested that ECMO improved survival in infants with an oxygenation index (OI) of >40.[170] However, with improving intensive care strategies, the need for ECMO has been reduced.[165] There has been interest in the protective effects of hypothermia for lung conditions such as MAS, and some centers have started to incorporate it into the management of these infants.[171]

## Prevention

There is an inverse association between amniotic fluid volume and fetal HR decelerations, possibly due to either cord or head compression. Amnioinfusion has been thought to dilute meconium, especially in cases of thick MSAF, and correct oligohydramnios, thereby relieving umbilical cord compression.[172] However, results of a meta-analysis suggested that amnioinfusion did not improve perinatal outcomes in settings of standard peripartum surveillance and was only beneficial in settings with limited facilities to monitor the baby during labor.[172] Furthermore, amnioinfusion carries increased risk of several adverse outcomes, including cord prolapse, infection, and requirement for instrumental delivery. There has been much debate in the value of meticulous clearing of the airway during and after delivery in an infant delivered through MSAF,[173] with recommendations being based more on biologic plausibility and expert opinion than a strong body of evidence. Avoidance of postterm delivery is the key factor in reducing the incidence of MSAF and thus MAS. With increasing numbers of studies and meta-analyses, there has been a failure to obtain evidence that routine efforts to clear the airway of meconium by ET or oropharyngeal suctioning can prevent MAS or lead to improved outcomes of affected infants.[174] It has been argued that MAS incidence in these studies was low. However, even in a setting with a high incidence of MAS, intrapartum suctioning was not shown to be of benefit.[175] In another recent study in a developing setting, ET suctioning was not shown to be superior to routine resuscitation even for nonvigorous babies delivered through MSAF.[162] Because of the accumulating evidence of lack of benefit of routine suctioning to prevent MAS, ILCOR no longer recommends routine ET suctioning of nonvigorous babies delivered through MSAF.[176] Clinical judgement regarding the presence of significant airway obstruction should be exercised when deciding whether to initiate ET suctioning, taking care not to delay PPV and other important resuscitation measures in the process.

## Prognosis

The mortality of MAS in a developed setting has been reported to be 2.5%.[157] In contrast, mortality can be as high as 32% in developing regions of the world.[177] Most deaths are from respiratory failure, pulmonary hypertension, or air leaks. Fifty percent of babies who require mechanical ventilation because of MAS suffer an air leak. Neurodevelopmental delays have been observed even in infants who respond well to conventional ventilation.[178] Children with a history of MAS have been found to exhibit long-term lung function abnormalities, increased bronchial hyperreactivity, and higher reported rates of recurrent cough and wheeze.[179]

# Acute Respiratory Distress Syndrome

## Pathophysiology

Acute respiratory distress syndrome (ARDS) in the newborn occurs when a systemic injury leads to lung inflammation and injury in previously healthy lungs and is often associated with multiorgan failure.[180] Like adults, ARDS can occur following asphyxia, shock (cardiogenic or hypovolemic), or sepsis. Myocardial dysfunction from birth asphyxia or from severe metabolic acidosis can lead to pulmonary edema and need for ventilator support. The direct injury from the hypoxia on the lung tissue or the injury sustained from mechanical ventilation leads to release of proteins into the air spaces, thus worsening the lung disease by inactivation of surfactant.[105] Sepsis will lead to increased capillary leak of fluid and protein into the lungs. Preterm infants may be predisposed to lung inflammation from chorioamnionitis, and severe chorioamnionitis may have systemic responses—fetal inflammatory response syndrome (FIRS).[181]

## Clinical Presentation

ARDS presents with worsening tachypnea and oxygen requirements after a systemic event. Clinically it may look very like primary lung diseases such as pneumonia or MAS (discussed in other sections of this chapter). Some infants who have the clinical appearance of RDS, but who are not premature and do not have a good response to exogenous surfactant therapy, may have underlying lung disease more consistent with ARDS. The tachypnea may result initially from stimulation by metabolic acidosis or damage to the central nervous system, but the hypoxia will progressively worsen as the lung tissue becomes edematous and inflammation develops. The chest radiograph demonstrates diffuse pulmonary infiltrates, with some severe cases having complete opacification of the lungs. Blood cultures and tracheal aspirates may guide the antibiotic management of these infants.

## Management

Treatment of the underlying cause of the ARDS (sepsis, birth asphyxia, cardiogenic shock) is essential for the lungs to recover. The newborn lung is moderately resistant to chronic injury and should be able to recover if the infant can survive the initial insult. Surfactant administration can improve oxygenation in ARDS, similar to MAS, but may require larger doses than used in RDS.[180] Efforts to increase the mean airway pressure, through either higher PEEP or longer inspiratory time, will help to increase FRC and improve oxygenation. HFOV, especially when using a series of recruitment steps to reach an open lung, may have benefits for improving oxygenation in ARDS though its superiority over conventional ventilation has not been demonstrated.[182] In recent studies in adults with ARDS, HFOV did not decrease mortality over conventional mechanical ventilation.[183] Fluid management is important in treating ARDS as the clinician tries to decrease flooding of the lung with fluid restriction, while still maintaining proper perfusion of other organs. Broad-spectrum antimicrobials (usually ampicillin plus an aminoglycoside if in the first few days after birth but with broader coverage, especially for staphylococcus, when systemic infection is suspected after 3 days) should be administered. Aminoglycoside levels must be carefully monitored because these infants are at high risk of renal dysfunction. Air leaks and infection are commonly seen in infants with ARDS. Pulmonary hypertension can occur in ARDS and infants may benefit from sedation or inhaled NO therapy. Severe ARDS that does not respond to HFOV may require ECMO, often arteriovenous due to cardiac dysfunction, until the lungs recover. The mortality and morbidity of ARDS are high, and this is due to a combination of the hypoxia from the lung disease and the effects of the systemic disease that caused the ARDS.

## Early-Onset Pneumonia

Early-onset pneumonia presents clinically within the first 48 hours to 1 week after birth.[184] Because early-onset or congenital pneumonias are often present at birth, it is sometimes difficult to distinguish pneumonia from RDS, TTN, or MAS. Radiographically diagnosed pneumonia was found in 1.5% of infants born at 34 weeks versus 0.2% of infants born at term.[185] Pneumonias can be acquired either transplacentally from mother, during labor with prolonged rupture of membranes or chorioamnionitis, or during delivery. The timing of clinical presentation will depend on the mode of transmission. The term newborn lung is immature with respect to ciliary clearance of microbes, lung macrophage function, and humoral immune responses (immunoglobulin A, surfactant protein A and D); and this predisposes the newborn lung to pneumonias. Although originally thought to be sterile, the normal lung is now known to be colonized with its own microbiome and the interactions between normal and pathologic bacteria may play a role in the development of pneumonia or other respiratory diseases.[186] The mode of delivery affects the respiratory microbiome, with infants delivered vaginally having bacteria closer to the mother's vaginal secretions, whereas C-section infants have a lung biome closer to maternal skin.[186] Transplacentally acquired organisms associated with pneumonia include *Listeria monocytogenes* (often found in unpasteurized cheeses), *Mycobacterium tuberculosis, Treponema pallidum,* rubella virus, cytomegalovirus (CMV), herpes simplex virus (HSV), adenovirus, and influenza type A virus. A high percentage (more than 20%) of stillborn infants or infants that die soon after birth are found to have pneumonia at autopsy.[184] Most cases caused by ascending infection are due to *Streptococcus agalactiae* (GBS), and antenatal testing for GBS is recommended for all pregnant women. The use of antenatal GBS prophylaxis has decreased the rates of early onset GBS sepsis and pneumonia but has not changed the rates of late-onset disease. There are 10 identifiable subtypes of GBS based on capsular polysaccharide antigens; most neonatal infections are caused by types Ia, II, III, and V, but the pathogenic subtypes differ between countries.[187] The incidence of early-onset GBS sepsis is 0.67 per 1000 live births in the Americas and 0.53 per 1000 in Europe. Countries reporting no use of intrapartum antibiotics have had a 2.2-fold increase in early-onset disease.[187] *E. coli* is the second most common cause of early-onset neonatal sepsis and pneumonia.[188,189] A large percentage of *E. coli* strains that cause early-onset sepsis possess the capsule type K1, which confers antiphagocytic properties and resistance to complement mediated killing; antibiotic resistance to both ampicillin and gentamicin have been increasingly reported in *E. coli.* Other organisms that cause ascending infection include *Haemophilus influenzae, Streptococcus pneumoniae, L. monocytogenes, Klebsiella pneumoniae, Candida albicans,* and viruses such as adenovirus, CMV, HSV, and echovirus.

Risk factors for early-onset pneumonia include prolonged rupture of the membranes, premature labor, and colonization of the vagina with GBS or other pathogens. Chorioamnionitis increases the risk of early-onset pneumonia and may predispose the infant to an altered immune/inflammatory response to microorganisms acquired during labor.[189] In developed countries, approximately 20%–30% of women are colonized with GBS in the vaginal vault and 50% of infants born vaginally will become colonized. Fortunately, only 1% of these infants will develop invasive GBS disease.[187] Although not routinely tested clinically, the highest transmission rate is in GBS colonized women who have low levels of circulating anti-GBS immunoglobulin. Women infected with HIV are considerably more susceptible to many perinatal infections, especially *L. monocytogenes.* HSV is usually transmitted during delivery through an infected maternal genital tract.

## Clinical Presentation

The timing of presentation depends on whether the infection was acquired transplacentally, usually present at birth, or during labor, when it may take up to 48 hours to develop. GBS is a fast-growing microorganism, and most of these infections will present in the first

12 hours, and rapid deterioration can occur without prompt treatment. In the setting of chorioamnionitis, sepsis may present within 6 hours of birth.[189] Many infants with pneumonia or sepsis have normal Apgar values at birth but develop progressive tachypnea, respiratory distress, hypoxia, and other signs of sepsis. Some infants will have more subtle findings, such as poor feeding, irritability, hypothermia, or fever.[152] Infants who are overtly septic with poor peripheral perfusion, cyanosis, and inadequate respiration have a poor prognosis.[189] Infants with severe congenital pneumonia may require high PIPs to open the inflamed lungs. Infants with congenitally acquired Listeria infection are often extremely ill at birth, with severe pneumonia and hepatomegaly, and at autopsy have small pinkish-gray granulomas throughout the lung, liver, skin, and other organ systems. Viruses such as CMV and HSV can present with pneumonia or more generalized pneumonitis.

The chest radiograph appearance is variable and can range from an entire lobe (Fig. 19.5) to segmental consolidation, atelectasis, or diffuse opacification (Fig. 19.6). Many pediatric radiologists will not distinguish between neonatal pneumonia, TTN, or RDS, and often a follow-up image is needed (TTN should have resolved on repeat x-ray). Pleural effusions can be present and sometimes abscesses or pneumatoceles. For intubated infants, a tracheal aspirate from a new ET tube can sometimes be useful and should be evaluated by microscopy for white blood cell, and culture. Blood cultures are important because many of the infections are hematogenously spread or have secondary bacterial release into the bloodstream. Systemic markers of infection and inflammation, such as a CBC or C-reactive protein, may help to guide the clinician regarding antibiotic use. In the setting of suspected chorioamnionitis, histologic evaluation and culture of the placenta may provide additional information on the organism. If herpes infection is likely, viral cultures from the maternal lesions and the infant should be obtained.

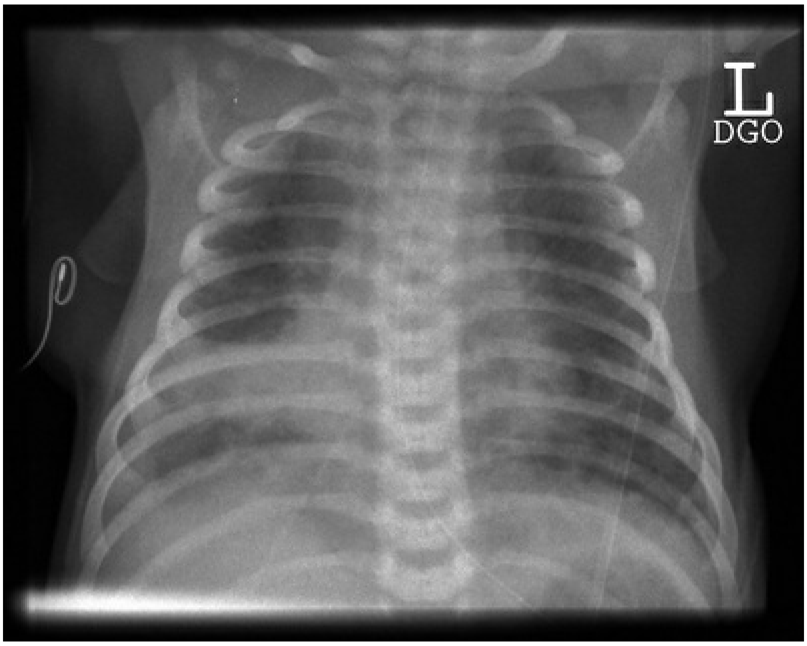

**FIG. 19.5** Lobar pneumonia: right lower lobe is consolidated on chest x-ray and streaky infiltrates can be seen in other portions of the lungs.

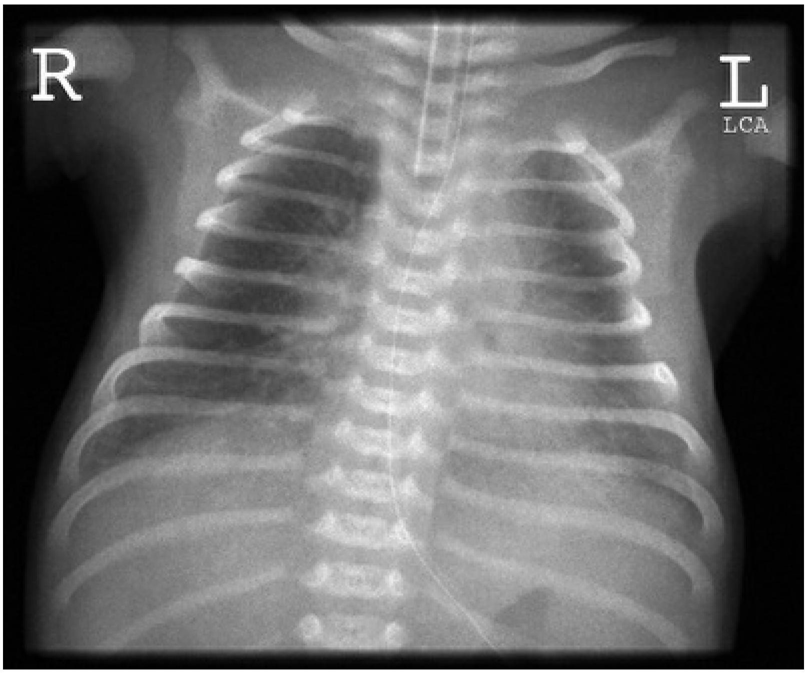

**FIG. 19.6** Newborn pneumonia. Diffuse opacifications are visible throughout lungs. Clinical correlation will often determine pneumonia verses transient tachypnea of the newborn or respiratory distress syndrome.

## Management

Because it is difficult to determine whether respiratory distress is caused by pneumonia or TTN, many clinicians will treat any respiratory distress requiring additional monitoring with antibiotics. All infants who were well appearing at birth and then develop respiratory distress require a work-up for sepsis, pneumonia, and congenital heart disease. Initial treatment for early-onset pneumonia should be a combination of ampicillin or benzylpenicillin and an aminoglycoside, most often gentamicin. The initial management regiment should be modified once culture results are available, or if certain resistance patterns are present within the local community. Cefotaxime can be substituted for gentamicin in infants with birth asphyxia or concerns about renal failure. Certain bacteria, such as *H. influenza,* may require cefotaxime due to development of antibiotic resistance. *E. coli* is often resistant to ampicillin, and bacterial strains resistant to both ampicillin and gentamicin have been reported. For Listeria, the most effective antimicrobial therapy is the combination of ampicillin plus gentamicin because Listeria is resistant to all cephalosporins. The length of treatment depends on the severity of the disease, the presence of systemic response, and the organism isolated. Most early-onset cases of pneumonia will respond to antibiotic therapy of 7–10 days, with no clear evidence for one treatment length or the other. Lung abscesses and empyemas should be drained, and with these complications IV antimicrobials should be administered for at least 2 weeks. Infections due to HSV require long-term therapy with high-dose acyclovir.

# Late-Onset Pneumonia

Late-onset pneumonia typically occurs in infants after approximately 1 week to 3 weeks of life and can be caused by a variety of bacteria and respiratory viruses. The most common causes are gram-positive cocci (coagulase-negative Staphylococci, *Staphylococcus aureus,* streptococci) and gram-negative bacilli (including *Klebsiella, E. coli, Serratia marcescens,* and *Pseudomonas*). These infections often occur in infants with prolonged mechanical ventilation, and hospitals have developed respiratory hygiene protocols to attempt to decrease ventilator-associated pneumonias.[190] Increasing respiratory support while on mechanical ventilation should be investigated for development of pneumonia. *Chlamydia trachomatis* is a well-recognized cause of late-onset pneumonia, often presenting at 1–3 months of age, and may develop in 7% of infants born to mothers infected with Chlamydia.[184] Two weeks of oral erythromycin is recommended for chlamydial pneumonia. *Ureaplasma urealyticum* is a common cause of chorioamnionitis and pneumonia in infants, but the bacterium does not grow well on typical culture media and is often not identified. In areas of the world where tuberculosis is prevalent, tuberculosis pneumonia should be considered because the symptoms are nonspecific, and tuberculosis can be acquired by transplacental spread, aspiration, ingestion of infected amniotic fluid, or airborne inoculation from close contacts.[184] Respiratory viruses have an increasing role in late-onset pneumonia, with adenovirus, rhinovirus, respiratory syncytial virus, influenza, and human metapneumovirus being the most common. With the use of respiratory virus polymerase chain reaction (PCR) panels, many previously undiagnosed infections can be found and proper isolation of the infant can be instituted. Viral pneumonias are often nosocomial and usually occur when there are high levels of infection in the community. Fungal pneumonias, often due to candida species, can be found in very low birth weight (VLBW) infants, especially after prolonged exposure to third-generation cephalosporins, but are typically caused by hematogenous spread. CMV pneumonia is rare in the term infant but can be a cause of persistent CMV pneumonitis in immunocompromised or very preterm infants. CMV can be acquired from CMV-infected amniotic fluid or through feeding with thawed frozen breast milk from HCMV-Ig–positive mothers.[191] Although many of the bacteria that cause late-onset pneumonia are covered by the combination of ampicillin and gentamicin, initial treatment with a third-generation cephalosporin and vancomycin may be warranted. If the infant is worsening on current antimicrobials, the regime should broadened to cover nosocomial organisms such as *Pseudomonas* and *Serratia*.[184]

## Aspiration Pneumonia

Aspiration pneumonia occurs in newborns either through aspiration of GER into airways or from inappropriate closure of the airways during feedings. The aspirated fluid can cause inflammation of the airways or cause physical obstruction of the airways.[192] The airway obstruction can lead to lung collapse or increased propensity for bacterial infection (Fig. 19.7), with the right upper lobe being the most affected region. The low pH of gastric secretions may lead to worsening chemical irritation of the airways and lung parenchyma. Infants with chronic microaspirations may develop hypoxia and respiratory distress.[193] Severe aspiration pneumonia often requires mechanical ventilation until inflammation has resolved. Broad-spectrum antimicrobial cover should be prescribed for aspiration pneumonia with consolidation but may not be necessary for microaspiration. Infants with consolidation of the right upper lobe may benefit from positioning this side up to allow increased aeration and drainage of the lung segment. Aspiration pneumonia is more common in infants with neurologic disease or injury, and surgical intervention with Nissen procedure or gastrostomy tube may be necessary to prevent recurrent events.[194] Preterm infants with BPD and a developmentally normal neurologic examination can be fed while on CPAP without increased risk of aspiration pneumonia.

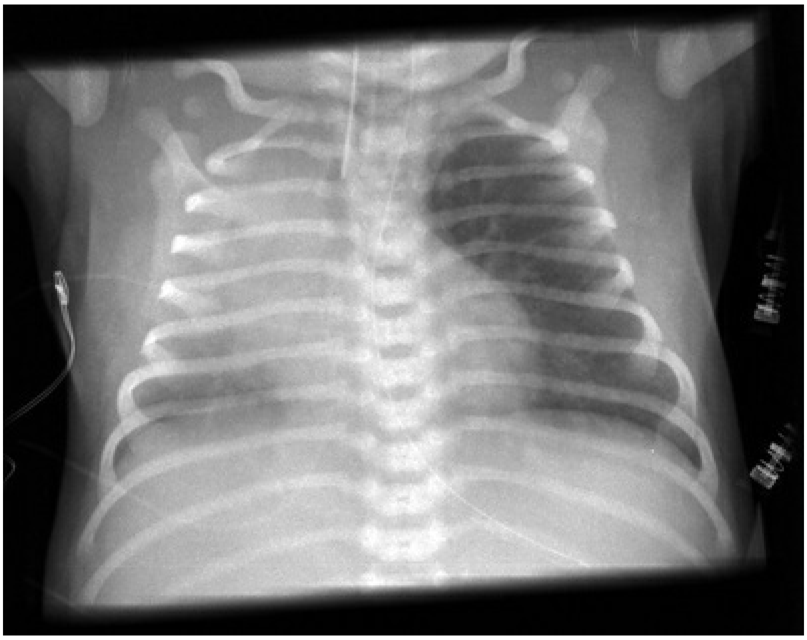

**FIG. 19.7** Aspiration pneumonia: aspiration often causes lobar pneumonitis or pneumonia. The right upper lobe is most often involved.

## Interstitial Lung Disease

Childhood interstitial lung disease (chILD) should be in the differential of term newborns with severe respiratory distress, or preterm infants with prolonged ventilator support that do not have normal responses to surfactant therapies. These conditions include problems with the surfactant system (e.g., surfactant protein deficiency and ABCA3 deficiency—reviewed in Chapters 5 and 57), pulmonary interstitial glycogenosis (PIG), neuroendocrine cell hyperplasia of infancy (NEHI—previously called persistent tachypnea of infancy), or alveolar capillary dysplasia (ACD). Interstitial lung disease is diagnosed through high-resolution computed tomography (CT) scan or lung biopsy. Corticosteroids are commonly used in many chILD and may decrease lung inflammation and interstitial thickening. Interstitial lung disease is covered in detail in Chapters 54–57.

## Persistent Pulmonary Hypertension of

# the Newborn

PPHN is caused by failure of the pulmonary vascular resistance (PVR) to rapidly decrease at birth, leading to right-to-left shunts at the level of the ductus arteriosus and the foramen ovale and difficulty with oxygenation. Although PPHN is sometimes referred to as persistent fetal circulation, the removal of the low-resistance, high-volume placental circuit creates additional work for the cardiopulmonary system. Understanding the alterations in the normal physiologic transition at birth helps clinicians to develop therapeutic interventions for these critically ill infants.

## Changes in the Circulation at Birth

During fetal circulation, the PVR is high and only 10%–20% of the cardiac output goes through the pulmonary vasculature. The low resistance, high volume of the placenta enhances shunting of the blood away from the lungs through the foramen ovale or the ductus arteriosus. Pulmonary blood flow and PVR changes throughout the pregnancy in a U-shaped curve. The PVR is high at 20 weeks GA, with 13% cardiac output going to lungs, then PVR drops around 30 weeks gestation to increase blood flow to lungs to 25%–30% of cardiac output, before an increase in PVR near term causes a drop in pulmonary blood flow to around 20%.[195] The combination of increased arterial oxygen content, removal of the low resistance of the placenta, and removal of placental derived prostaglandins lead to rapid transitions from fetal to newborn circulations. Removal of the placenta decreases venous return to the right atrium, decreases right atrial (RA) pressure, and increases systemic vascular resistance (SVR) leading to increased left atrial pressure, which leads to closure of the foramen ovale. The flow through the ductus arteriosus decreases such that it passively closes within 3–7 days after birth. In normal newborns, PVR falls rapidly in the first minutes after birth, with recruitment of FRC and then more gradually over the next days. Aeration of the lungs, through stimulation of stretch receptors, vasodilates the pulmonary vascular bed and increases the pulmonary blood flow.[196,197] Opening of the alveoli also leads to decrease perivascular fluid and improved gas exchange (see clearance of airway fluid). *In utero* the PVR remains high due to low levels of pulmonary vasodilators (oxygen, prostacyclin [$PGI_2$] and NO), and high levels of vasoconstrictors (endothelin-1 [ET-1]).[198] $PGI_2$ is produced by the vascular endothelial cells, pulmonary stretch increases its release, and causes relaxation of smooth muscle surrounding the arterioles. Blockade of prostaglandins *in utero* does not affect resting PVR, whereas exogenous $PGI_2$ causes vasodilation after birth.[199] NO is also produced by the vascular endothelial cells through the cleavage of L-arginine by NO synthase. NO diffuses into the smooth muscles cells to stimulate vessel relaxation through production of guanosine monophosphate. Because oxygen tension helps to regulate NO production, fetal NO levels are low in the relative hypoxic environment. Endogenous NO production responds to the increased $PaO_2$ associated with initiation of ventilation at birth. $PGI_2$ activity may be modulated by NO because NO synthase inhibitors decrease the effectiveness of exogenous $PGI_2$. Along with increasing vasodilators, endogenous vasoconstrictors (thromboxane and ET-1) decrease at birth to allow relaxation of the vasculature. In newborns with significant hypoxia or sepsis, levels of ET-1 and thromboxane A2, along with leukotrienes, are increased and can cause severe pulmonary hypertension. Prostaglandin $E_2$, which helps to maintain ductal patency *in utero,* is produced by the placenta and $PGE_2$ metabolism within the lungs is enhanced by ventilation, thus decreasing levels of $PGE_2$ help to facilitate ductal closure. Although there is some variation, most infants complete this cardiovascular transition by 8 hours of age and the ductus arteriosus typically closes by 24 hours of age. Pulmonary vascular pressure decreases to 50% of systemic vascular pressure by 24 hours of life, and adult levels of PVR are typically reached by 6 weeks of age.[198]

## Pathophysiology

PPHN can be secondary to systemic conditions (birth asphyxia, sepsis, metabolic disorders, maternal exposure to selective serotonin reuptake inhibitor, BPD) or due to congenital conditions

(CDH, congenital heart disease, ACD, pulmonary hypoplasia). There is an increased incidence of pulmonary hypertension in some genetic disorders (trisomy 21, Noonan syndrome, DiGeorge) and with rare familial mutations.[200] The newborn pulmonary vasculature responds quickly to changes in pH, $PaO_2$, and $PaCO_2$. Acidosis (either respiratory or metabolic) leads to pulmonary vasoconstriction, whereas alkalosis can temporarily improve PVR and oxygenation. Caution should be used with induction of chronic respiratory alkalosis, because overventilation and hypocapnia can injure the lung and may potentiate cerebral vasoconstriction.[200] Hypoxia also causes pulmonary vasoconstriction, with $PaO_2$ levels less than 60 mm Hg causing exponential increases in PVR.[201,202] Intrauterine growth restriction infants with chronic hypoxia and placental insufficiency also have increased muscularization of the pulmonary arterioles and extension of muscle layer into smaller arteries. Hypoxia leads to increase in vasoconstrictor and smooth muscle mitogens (ET-1, platelet-derived growth factor B, vascular endothelial growth factor) and decreases in endothelial NO synthase.[203] In the setting of meconium aspiration, where the release of meconium is a response to *in utero* stress and chronic hypoxia over a period of days, there may be changes to the vascular walls that contribute to pulmonary hypertension. Higher hematocrits (Hcts) have also been associated with increased pulmonary hypertension, but this may be due to changes from fetal hypoxia that also stimulate red cell production. ACD (discussed in Chapter 56) cause disruption of the alignment of the pulmonary vasculature with the distal airspaces, creating pulmonary hypertension and failure to oxygenate. Infants with pulmonary hypoplasia, due to either physical obstruction in CDH or from loss of distending pressure in severe oligohydramnios, have decreased arteriole numbers and increased musculature. These infants often have both a fixed anatomic component and a reactive component (responds to treatments listed later) to their pulmonary hypertension creating a mixed response to treatment. Infants with PPHN typically have a normal number and muscularization of the arteries, but the arterioles fail to respond to normal transitional cues of increased oxygen tension and expansion of the lung at birth. PPHN is more common in infants with African-American or Asian mothers, and who are male.[204] With current therapies, the PVR of most infants will eventually decrease over the first week. Prolonged need for treatment warrants further evaluation for rare conditions such as ACD or surfactant deficiency.

## Clinical Presentation

Infants with PPHN usually present within 6 hours of birth with cyanosis and mild respiratory distress. Because the lungs are often fully expanded in PPHN, grunting and nasal flaring are uncommon with these infants. On cardiac examination, the second heart sound may be louder due to the increased pulmonary pressures and there may be a soft systolic murmur from tricuspid regurgitation (TR). Infants with pulmonary hypertension from structural changes to the lung parenchyma (CDH, pulmonary hypoplasia) will present with increased respiratory symptoms and other physical examination findings associated with these conditions. Pulmonary hypertension can occur in severe GBS infection and birth asphyxia, and these infants may have systemic signs of shock or neurologic changes.

## Diagnosis and Differential Diagnosis

Pulmonary hypertension should be suspected when the severity of hypoxemia does not correspond to the severity of radiologic or clinical symptoms. Infants with pulmonary hypertension secondary to other systemic diseases may have radiographic changes consistent with the original disease process. Evidence of right-to-left shunting across the ductus arteriosus can be determined by pulse oximetry readings between the right wrist (preductal) and the lower extremity (postductal). $PaO_2$ levels can be compared between a radial artery and the umbilical artery, but this is normally not necessary due to the reliability of saturation differences on pulse oximetry. Response to oxygen therapy is more common in pulmonary hypertension than congenital heart disease, although some infants with severe PPHN will have $PaO_2 < 100$ mm Hg on 100% oxygen. Infants with congenital heart disease may have a similar presentation, so echocardiogram is necessary to rule out structural heart disease. Although cardiac catheterization is the only way to directly measure pulmonary arterial pressures, echocardiogram is primarily used clinically to diagnosis pulmonary hypertension.[200] The TR jet velocity is the most accurate echocardiographic predictor of pulmonary hypertension in children.[200] Because many infants do not have a measurable TR, other echocardiographic findings in PPHN include RA enlargement, right ventricular (RV) dilation, pulmonary artery dilation, septal flattening, and directional shunting at PFO or PDA.[200] Infants with fixed pulmonary hypertension from congenital changes to the lung (CDH, lung hypoplasia) may not respond to oxygen therapy. ACD should be suspected in infants with severe pulmonary hypertension that is persistent and unresponsive to conventional therapies, but it requires a lung biopsy to establish the diagnosis. The severity of the pulmonary hypertension can be measured by either oxygen index or alveolar-arterial oxygen difference, and these parameters can be used to determine response to therapies and need to escalate care towards ECMO.

## Management

Overstimulation can worsen pulmonary hypertension and oxygenation in infants with PPHN. Minimal handling by staff and family and reduction in nursing interventions such as routine ET suctioning can improve oxygenation. The infant should be maintained in a normothermic environment, unless undergoing therapeutic hypothermia for birth asphyxia, because extremes of temperature can alter PVR. Because sepsis and neonatal pneumonia are often causes of pulmonary hypertension in the newborn, broad-spectrum antibiotics should be considered in the initial days of treatment. The infant's Hct should be maintained in a normal range (40%–50%) to optimize oxygen delivery without causing the increased viscosity and PVR seen with polycythemia.[203] In situations of extreme polycythemia (Hct > 70%), a partial exchange transfusion should be considered. Many infants with moderate to severe pulmonary hypertension will require continuous sedation and pain control to improve oxygenation. In some situations, pharmacologic paralysis can be used to reduce PVR and prevent

ECMO use; up to 73% of infants received paralysis prior to routine NO use.[205]

Two of the most basic therapies for PPHN, available in low-resource environments, are optimizing lung expansion and oxygen therapy. Many infants with mild PPHN can be treated with nasal cannula oxygen to decrease PVR. Maintaining lung expansion and avoiding atelectasis is important for improving ventilation-perfusion mismatch in PPHN and can often be achieved with CPAP. Infants with moderate to severe PPHN normally require intubation and mechanical ventilation. The addition of surfactant to infants receiving mechanical ventilation, especially in the setting of meconium aspiration, should be considered.[200,206] Surfactant therapy has been shown to reduce the need for ECMO in MAS, but not in PPHN. Current European guidelines for management of acute PPHN recommend maintaining partial pressure of carbon dioxide ($pCO_2$) between 45 and 60 mm Hg and $pH > 7.25$.[206] Lower pH levels increase the reactivity of the pulmonary vasculature to hypoxia. Alkalosis, either by mechanical ventilation to induce hypocapnia or through metabolic alkalosis with sodium bicarbonate, can transiently increase oxygenation. Hyperventilation, once a main therapy in PPHN, is not routinely recommended because prolonged alkalosis can worsen lung disease and can cause changes in cerebral blood flow and neurodevelopmental outcome.[200,205] Lung overdistention from high inflating pressure and PEEP can also cause barotrauma and worsening of pulmonary hypertension. Some centers use high-frequency oscillation or jet ventilation to maintain higher mean airway pressures to keep the lungs inflated. ECMO is used as a rescue therapy for infants unresponsive to additional therapies listed later. Oxygen is the other main therapy for PPHN available in most parts of the world. Oxygen is a potent vasodilator of the pulmonary vasculature, and this drug should be titrated in infants with PPHN to both avoid hypoxia and hyperoxia. Hypoxia causes vasoconstriction in animals at $PaO_2 < 50$ mm Hg with exponential increases in PVR as hypoxia worsens.[202] Increasing $PaO_2$ to greater than 60 mm Hg does not decrease the PVR further. High oxygen tension can lead to free radical formation and worsening of the pulmonary hypertension. NO is directly inactivated by superoxide forming peroxynitrite which is toxic, and hyperoxia enhances phosphodiesterase-5 (PDE-5) activity, leading to increased break down of NO. Hyperoxia can also cause vasoconstriction through activation of xanthine oxidase.[207] To avoid hypoxia and hyperoxia, infants with PPHN are recommended to be maintained at an oxygen saturation by pulse oximetry ($SpO_2$) level between 90% and 95% with avoidance of $SpO_2$ levels less than 85 or greater than 97%.[200,206,207] These saturation levels correspond to a $PaO_2$ of 60–80 mm Hg. Although many infants with mild to moderate PPHN can have oxygenation maintained through oxygen, CPAP, and sedation, an increasing OI should signal a need for a higher level of NICU care and initiation of therapies listed later.

iNO is the only US Food and Drug Administration (FDA)-approved gas for treatment of pulmonary hypertension in term and late preterm infants. iNO is typically bled into a ventilator circuit, although it can be given via nasal cannulae (NC) or CPAP in noninvasive ventilation. iNO diffuses across the capillary membrane into the vascular smooth muscle to relax the arterioles. iNO then binds to hemoglobin and is quickly converted to an inactive form leaving methemoglobin (metHg) and nitrite. This conversion limits the systemic effects of NO, making it a selective pulmonary vasodilator. MetHg is normally reduced by metHg reductase in erythrocytes, but this enzyme can be low in premature infants and some ethnic groups (Native Americans, Siberians, Turkish). Because MetHg poorly binds oxygen, metHg levels need to be followed on infants on NO. iNO has also been associated with an increased bleeding time and possible effects on surfactant function. For the treatment of PPHN, iNO is usually started at 10–20 parts per million (ppm) and has vasoactive properties as low as 5 ppm. Studies have compared 20 ppm and 80 ppm in term infants with PPHN and found no difference in the efficacy but an increased risk of metHg.[208] Guidelines recommend the use of iNO in infants with an $OI > 25$ or a $PaO_2 < 100$ mm Hg on 100% $FiO_2$.[200,206] iNO improves oxygenation and decreases the need for ECMO when started on infants with $OI > 25$ but has no effect on mortality or neurologic outcome.[200,206,207] Approximately 30% of infants do not have a sustained response to NO.[209] There are conflicting data on whether starting iNO when OI is >15 but <25 is beneficial.[200,207] The combination of surfactant and NO may lower OI. The use of HFOV has been advocated by some research groups because the open lung ventilation styles may decrease the ventilation-perfusion mismatch and improve iNO delivery.[200] Once the infants PVR improves, iNO should be weaned to avoid risks of metHg. iNO can be weaned quickly to 5 ppm but then should be slowly weaned to 1 ppm over a period of hours.[200] Abrupt discontinuation of iNO will lead to rebound pulmonary hypertension due to a decrease in endogenous NO production caused by the therapy. The use of iNO in premature infants is controversial. The NIH released a consensus statement in 2011 that discouraged the use of iNO is preterm infants, except in the infant with prolonged rupture of membranes or oligohydramnios, because of lack of efficacy.[210] Multiple large studies of preterm infants have been conducted to test if iNO could decrease BPD, but none have shown a benefit for lung disease or neurologic outcomes.[211]

Because more than 30% of infants do not have a sustained improvement in oxygenation with iNO, other medications have been used to decrease pulmonary hypertension in the newborn. Like iNO, these medications are designed to modulate the pathways discussed earlier ($PGI_2$, ET-1, PDE5) and have been used in adults with pulmonary hypertension (see Chapter 35). These medications can be given either intravenously or by nebulization with the mechanical ventilator. $PGI_2$ modulates vascular muscle contraction by increasing cyclic-adenosine monophosphate to cause relaxation. In adults, $PGI_2$ analogs (epoprostenol, treprostinil, iloprost, beraprost) play a vital role in treatment of pulmonary hypertension but are often given intravenously and can lead to systemic hypotension. To avoid systemic hypotension, epoprostenol and iloprost (the only FDA-approved $PGI_2$ analog for inhalation) can be nebulized through the ventilator and have shown good results in PPHN refractory to iNO.[199] Bosentan, an ET-1 antagonist, is used for chronic therapy in adults with pulmonary hypertension but is normally only available in an oral solution. In the setting of iNO, the addition of bosentan to infants with PPHN did not show additional effects.[199] One of the most common adjuvant therapies to iNO in PPHN is sildenafil.[200,206] Sildenafil, a PGE5 inhibitor, inhibits the breakdown of cyclic guanosine monophosphate (cGMP) (the secondary messenger of NO pathway) to inactive GMP in the vascular smooth muscles. Sildenafil, which is available in IV and oral forms, can be given in combination with iNO for PPHN or for helping wean infants from iNO.[199,200,206] Guidelines recommend that sildenafil should be considered as first-line therapy for PPHN in settings where iNO is not available.[200,206] Sildenafil is often used in infants with BPD and pulmonary hypertension, and adjustments have been made to FDA warnings about its use in pediatric patients.[199] Tolazoline hydrochloride and magnesium sulfate have been used with moderate success in PPHN, but their systemic effects and the availability of iNO have limited their use in recent years.

Maintaining adequate systemic blood pressure is crucial to the management of PPHN. The right-to-left shunt across the PDA and PFO is dependent on the ratio of the PVR to the SVR. Increasing the systemic blood pressure will decrease this ratio and divert blood into the pulmonary vasculature.[212] Management of systemic perfusion involves both the RV dysfunction due to increased afterload with pulmonary hypertension and left ventricular dysfunction from preload reduction due to decreased pulmonary return. Increasing SVR without increasing pulmonary resistance may be more difficult in some cases of pulmonary hypertension where increased muscularity of the arterioles, due to chronic in utero hypoxia, may create similar increases in PVR. Dopamine and epinephrine may have the highest risk of similar increases in both PVR and SVR but are often used to maintain systemic blood pressure in the setting of PPHN. Norepinephrine may have less effect on PVR than SVR and has been shown to improve oxygenation in PPHN.[212] Dobutamine improves cardiac contractility and at lower doses (2–5 micrograms/kg per minute) increases PVR. Milrinone, a selective phosphodiesterase-3 (PDE3) inhibitor, can improve cardiac output by increasing contractility and decreasing left ventricular afterload, and improve PVR through interactions with NO and $PGI_2$. In the setting of 100% O2, iNO upregulates PDE3, thus milrinone may have additional benefits in PPHN refractory to iNO.[199,200,212] Milrinone can cause systemic hypotension, which may limit its use in neonates; thus it is often used in combination with other vasoactive medications.

When medical therapies fail to improve oxygenation and OI remains higher than 40 (protocols differ between centers), ECMO can be used to treat PPHN.[200,203,206] ECMO is not advisable for PPHN in infants with chromosomal anomalies, lethal congenital malformations, uncorrectable heart defects, and major intracranial bleeds. Due to size limitations and increased risk of IVH, ECMO is not recommended for severe PPHN in preterm infants less than 34 weeks GA or less than 2000 g.[206] ECMO can be done via either venovenous or venoarterial methods, depending on the size and cardiac function of the infant, and many centers have protocols for duration of use of ECMO.[203] The chance of an intracranial bleed is 10%–15%, and adverse neurologic outcome may be due to the underlying hypoxia or the vascular compromise from ligation and cannulation. With the introduction of iNO, the use of ECMO for PPHN has dramatically decreased.

## Mortality and Morbidity

Before the use of ECMO and iNO, the mortality from PPHN was nearly 50%.[200,205] Even with advanced therapies, the mortality rate for PPHN remains between 8% and 10%.[200] The mortality rate varies according to the underlying condition. The mortality rate for PPHN, or pulmonary hypertension due to RDS or MAS, is lower than that of infants with septic shock (e.g., GBS). ACD is a uniformly fatal condition without lung transplantation. Infants with severe PPHN have increased risk for neurodevelopmental delays and audiologic impairment.

# Pulmonary Hypertension in Bronchopulmonary Dysplasia

BPD in the modern era, discussed in Chapter 20, is due to both alveolar and capillary simplification. Infants with BPD have increased risk of pulmonary hypertension (25%–37% of infants) and may progress to right heart failure.[213] Screening echocardiograms should be done on infants with established BPD.[200] In infants with BPD and increased PVR, oxygen saturations of 92%–95% may be appropriate.[200] iNO and sildenafil can be used to treat pulmonary hypertension with BPD.

## Pneumothorax

Spontaneous pneumothoraces likely occur in 1%–2% of newborn deliveries, but only 10% of them are symptomatic.[214,215] Elective C-section increases the risk of pneumothorax compared with spontaneous vaginal delivery, probably due to the increased fetal lung fluid present at birth.[215] PPV and ET intubation increase the incidence to almost 6%.[214] High transpulmonary pressure, generated by the first spontaneous breaths to clear the fetal lung fluid from the airways, can cause local overdistention of the alveoli and air leaks. Prematurity and congenital lung malformations increase the risk of pneumothoraces. Rarely, pneumothoraces are caused by direct trauma to the airways by suction catheters or ET tubes, but these injuries more often lead to pneumomediastinum.

Small asymptomatic pneumothoraces are often found on chest films taken for other reasons. Most small pneumothoraces can be monitored clinically without intervention. Larger pneumothoraces will present with respiratory symptoms, including tachypnea, retractions, and an oxygen requirement. Pneumothoraces large enough to cause a shift of the central structures of the chest (tension pneumothorax) will presents with severe desaturations and signs of shock. Breath sounds may be decreased with a pneumothorax, and transillumination with a fiberoptic light can be used to evaluate for pneumothorax (area with pneumothorax will appear brighter). If the infant is clinically stable, a chest radiograph should be obtained to determine the diagnosis. A moderately large pneumothorax will demonstrate absent lung markings and a collapsed lung on the ipsilateral side. Tension pneumothorax will have eversion of the diaphragm and displacement of the central structures to the contralateral side (Fig. 19.8). Congenital lung malformations, such as pulmonary lobar emphysema or congenital pulmonary airway anomalies, can appear like pneumothoraces (see Chapter 18) and should be included in the differential diagnosis of atypically appearing air within the chest.

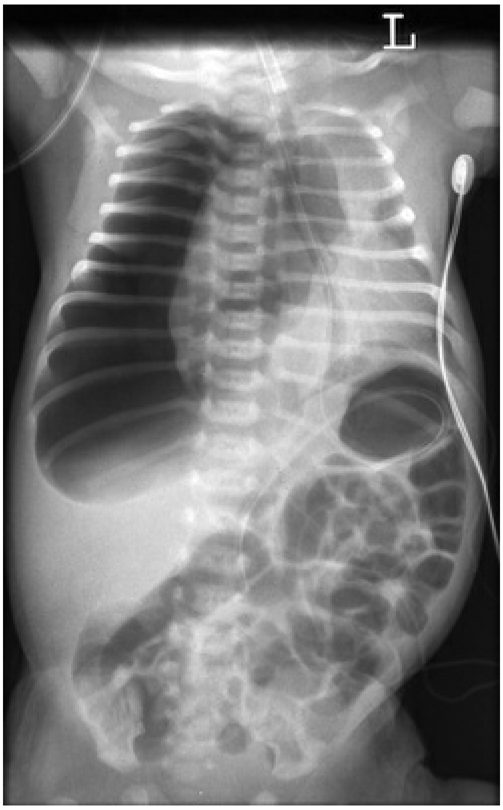

**FIG. 19.8** Tension pneumothorax: right-sided tension pneumothorax with collapse of the right lung, midline shift of the cardiac and trachea to the left.

Asymptomatic pneumothoraces do not require treatment and will reabsorb over time. Although many institutions use 100% oxygen for 6 hours to wash out the nitrogen in the pneumothorax, this practice has not been shown to decrease the time of resolution of pneumothoraces and may increase length of stay in the special care baby unit (SCBU).[216] In a cohort of infants >36 week GA with symptomatic spontaneous pneumothorax, approximately 71% could be managed with oxygen therapy, whereas 29% required thoracentesis or a thoracotomy tube.[217] Infants with significant respiratory distress or a tension pneumothorax require manual drainage of the pneumothorax. Immediate evacuation of the pneumothorax can be accomplished with an 18–22-gauge butterfly needle attached to a three-way stopcock and syringe. After cleaning with alcohol, the needle can be inserted into the second intercostal space above the rib at the midclavicular line and air aspirated. This can also be done through the mid-axillary region between the fourth and sixth ribs. In some larger infants, removal of the initial air by needle thoracentesis will be enough to resolve the pneumothorax. With larger pneumothoraces or reaccumulation of air after needle thoracentesis, a thoracotomy tube can be placed through the mid-axillary region and aimed in the direction of the pocket of air. Using sterile techniques and local anesthesia, either a standard chest tube (French gauge 10–14) or a pigtail angiocath can be inserted into the pleural space and positioned in the anterior chest (Fig. 19.9). The chest tube should be connected to an underwater seal drain with suction of 5–10 cm $H_2O$. Often the chest tube is removed from suction and placed to water seal for approximately 24 hours prior to removal of the chest tube.

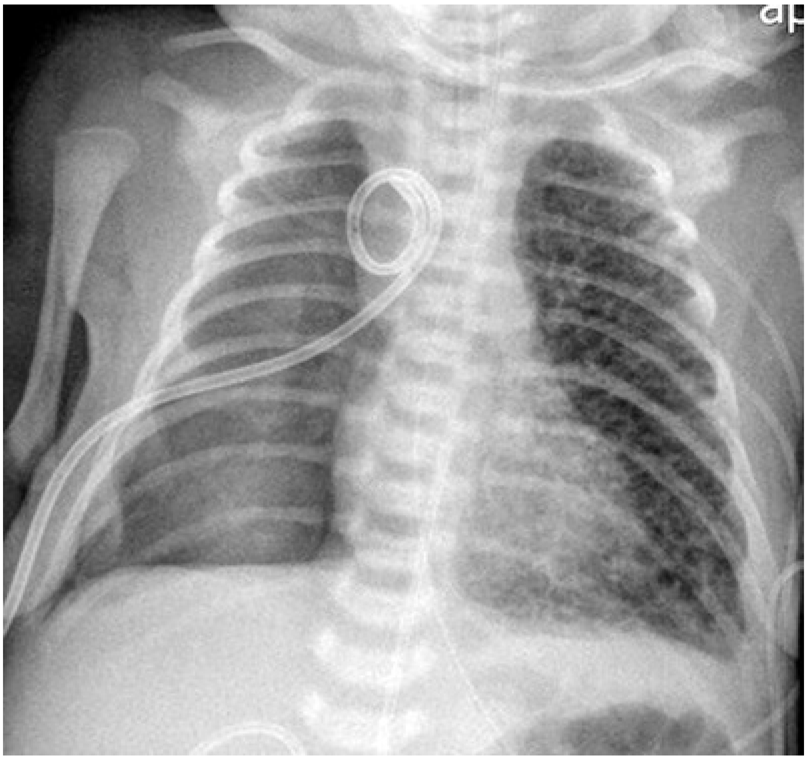

**FIG. 19.9** Pigtail catheter placement: chest tube catheter placed in right chest through axillary approach has resolved majority of pneumothorax. Small residual air is present on right chest and significant pulmonary interstitial emphysema is present on the left.

## Pneumomediastinum

Pneumomediastinum occurs in up to 2% of births, with similar risk factors to pneumothorax.[214] Most pneumomediastinums are asymptomatic and do not require treatment. On the chest radiograph, a pneumomediastinum is often seen near the borders of the heart or in the mediastinal region behind the sternum. The thymus can be elevated away from the central structures to form a spinnaker sail sign (Fig. 19.10) or the heart can be elevated off the diaphragm to create the appearance of a continuous diaphragm. Drainage of a pneumomediastinum is difficult because the gas is collected in multiple independent lobules. Because multiple vital vascular structures occupy the mediastinum, drainage should only be done in situations of severe respiratory distress.

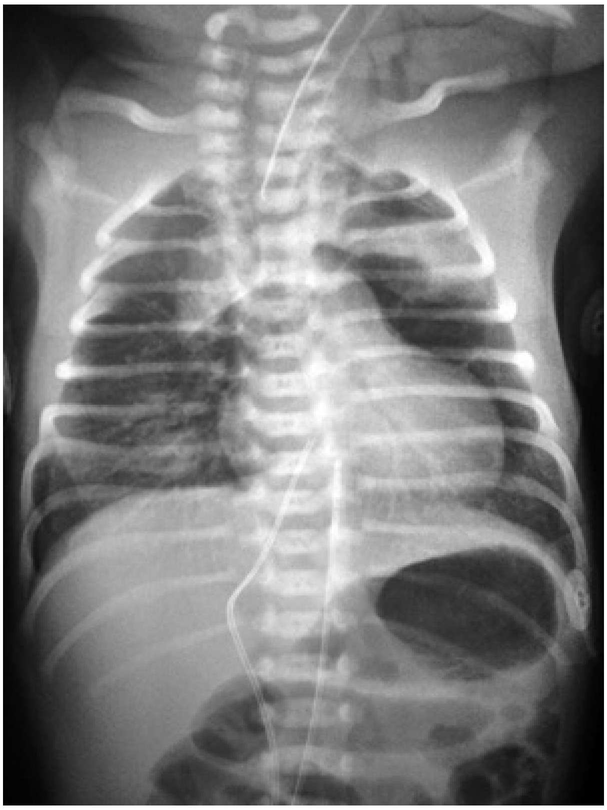

**FIG. 19.10** Pneumomediastinum: chest x-ray demonstrates air within the mediastinum causing upward displacement of the thymus (spinnaker sign).

## Pneumopericardium

Pneumopericardiums are rare and usually associated with other air leak syndromes. The gas, initially released into the space around the lungs, may dissect through a hole in the pericardial sac. It is more common in ventilated preterm infants and may be a consequence of severe PIE. Clinically, pneumopericardium presents with sudden hypotension and bradycardia due to cardiac tamponade. On chest radiograph, gas surrounds the heart and outlines the great arteries (Fig. 19.11). Infants with symptomatic pneumopericardium require immediate drainage due to impaired cardiac output. An angiocath or pigtail catheter can be inserted into the pericardial space using a subxyphoid approach. Blood pressure changes and bradycardia may suggest reaccumulation of the air within the pericardial sac. The mortality and long-term morbidity from pneumopericardium is high.

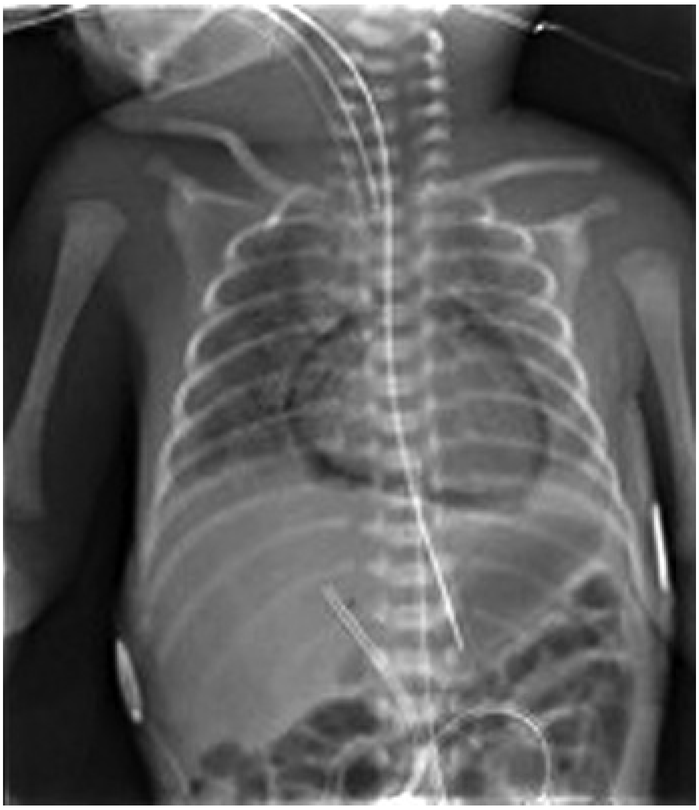

**FIG. 19.11** Pneumopericardium: often a medical emergency due to cardiac tamponade, the chest x-ray demonstrates air within the pericardium.

## Pulmonary Interstitial Emphysema

PIE is collection of air that escapes the alveoli and tracks along the sheaths of the small blood vessels of the lung. It rarely occurs spontaneously and is associated with PPV, especially with high pressures in small preterm infants. PIE occurs when the extraalveolar air remains within the lung parenchyma and does not escape into other regions of the chest (pneumothorax, pneumomediastinum, pneumopericardium, and rarely pneumoperitoneum). PIE commonly involves both lungs, but it may be lobar in distribution. The trapped gas can compress the vasculature and decreases pulmonary perfusion. The lung parenchyma is expanded leading to airway obstruction, increased lung compliance, and areas of hyperinflation. As a result, infants with severe PIE can be profoundly hypoxemic and hypercarbic on presentation. PIE is usually diagnosed by chest radiograph which demonstrates hyperinflation and diffuse, multiple, or small nonconfluent cystic radiolucencies (Fig. 19.12). Bilateral, diffuse PIE may have a narrow cardiac silhouette due to mediastinal compression. As the amount of air collects within the lung parenchyma, large bullae or pneumatoceles may form and are visible as circular air collections on the chest radiograph. Lobar emphysema and congenital pulmonary airway malformations are in the differential for these large cystic formations but are typically seen on earlier chest radiographs.

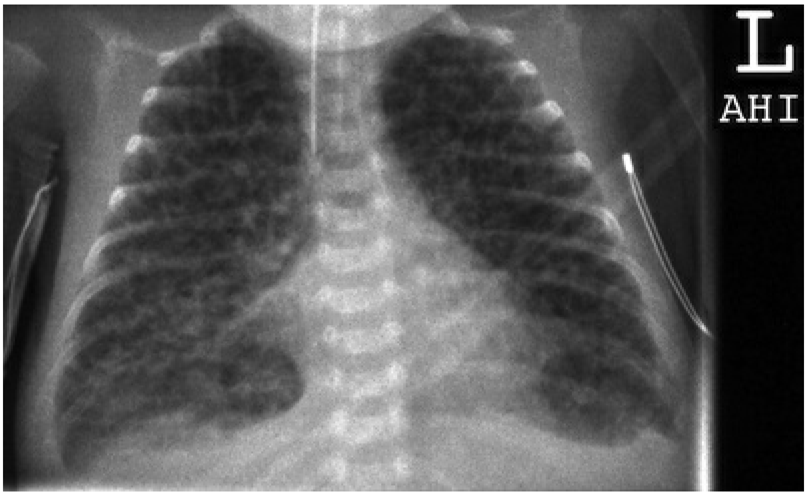

**FIG. 19.12** Pulmonary interstitial emphysema: small cystic changes throughout both lungs represent air dissection into the parenchyma.

If PIE is localized to one lobe of the lung, then placing the infant with this side down will cause partial collapse of the lung and may improve the PIE. This is not possible in severely ill preterm infants. Selective intubation of the opposite side from the PIE has been studied, but left mainstem intubation is often not possible in small infants. If the infant has diffuse PIE, the PEEP and peak inflating pressures should be reduced to the minimum compatible with acceptable oxygenation and ventilation. Pneumatoceles also respond to decreased ventilator pressures. HFJV and HFOV are often used clinically in PIE to decrease the pressure fluctuations within the injured lungs, but studies have not shown a conclusive benefit over conventional ventilation. One study supports the use of low-frequency settings (5–6 Hz) on HFOV to decrease severe PIE.[218] Overall, PIE is associated with severe lung disease in the preterm infant and is thus associated with high overall morbidity.

# Secondary Pulmonary Hypoplasia

See also Chapter 18.

## Epidemiology

The incidence of pulmonary hypoplasia is estimated to range from 9 to 11 per 10,000 live births.[219] Most cases are secondary in nature, with primary cases reported to be rare.[220] It is possible that mildly affected infants may not exhibit any clinical features, and thus the true incidence may be higher than reported.

## Etiology

The causes of secondary pulmonary hypoplasia may be divided into four main categories: (1) space-occupying lesions within the thoracic cavity (e.g., CDH, pulmonary sequestration, congenital pulmonary airways malformation [CPAM], and pleural effusions); (2) chest wall deformities leading to reduced intrathoracic space (e.g., asphyxiating thoracic dystrophy); (3) causes of severe oligohydramnios (e.g., bilateral renal agenesis, prolonged rupture of the membranes); (4) disorders impacting on normal lung development (e.g., neuromuscular disorders with reduced fetal breathing movements, congenital heart disease associated with abnormal pulmonary vasculature, large anterior abdominal wall defects affecting diaphragmatic, and chest wall development).[219,221–223]

## Pathogenesis

Lung development is a complicated process that has been shown to occur in stages.[219,224] The pseudoglandular stage takes place between approximately 6 and 17 weeks of GA and is the period when the conducting airways and initial acinar framework develop. The canalicular stage follows from approximately 17–26 weeks GA, during which further development of the lung parenchyma occurs. There is an increase in canaliculi, widening of the peripheral respiratory tubules with concurrent increase in pulmonary capillarization, forming the respiratory surface of the lung.[224] Disorders that impact lung development before 17 weeks GA also substantially impact lung growth, bronchiolar branching, cartilage development, acinar complexity, and capillarization. Disorders affecting lung growth during the canalicular stage (i.e., after 17 weeks GA) mainly affect acinar complexity.[219] Risk of pulmonary hypoplasia is much decreased by late canalicular stage, with higher risk of pulmonary hypoplasia associated with earlier insults. A review of 28 studies suggested that GA of preterm prelabor rupture of membranes was better associated with pulmonary hypoplasia than either degree of oligohydramnios or latency period.[225] A lack of intrathoracic space within which to grow and develop in the presence of space-occupying lesions or chest wall deformities is thought to physically limit the growth of the lungs. Further limitations in space can also impact fetal breathing movements and the usual movements of amniotic fluid in and out of the airways. This limitation in fetal breathing movements is also seen in infants with neuromuscular conditions, such as type 1 spinal muscular atrophy. Lack of adequate amniotic fluid can occur with all causes of severe oligohydramnios (e.g., bilateral renal agenesis) and prolonged and premature leakage of amniotic fluid, which has been shown to be associated with abnormal lung growth.[226,227]

## Clinical Features

A proportion of infants may be diagnosed antenatally. Pulmonary hypoplasia may be suspected if commonly associated conditions (e.g., oligohydramnios, CDH, or pleural effusion) are present. Once suspected, there are numerous antenatal features that have been reported to be useful to determine severity of pulmonary hypoplasia.[219,225] Of importance is the need to be able to distinguish between lethal and nonlethal forms. For example, investigators have suggested that persistent severe oligohydramnios after preterm prelabor rupture of membranes with onset <25 weeks GA was associated with greater than 90% mortality from pulmonary hypoplasia.[219] Other antenatal parameters include ultrasonic detection of absence of fetal breathing movements and biometric indices, such as thoracic circumference to abdominal circumference ratio, thoracic circumference to head circumference ratio, thoracic area minus heart area and thoracic area to heart area ratio. More recently, other imaging modalities, such as magnetic resonance imaging (MRI), have been explored.[228]

After birth, infants with secondary pulmonary hypoplasia can present with the clinical features of the condition to which the hypoplastic lung is secondary. For infants where the pulmonary hypoplasia is not associated with an intrathoracic space-occupying lesion, the chest wall may appear disproportionally small compared with the overall size of the infant. For those with underlying conditions not immediately apparent, the hypoplasia may be clinically undetectable, but, in those who present, the signs may range from tachypnea and mild respiratory distress to severe hypoxemic respiratory failure requiring ventilatory support with high ventilatory pressures. Chest radiography may reveal crowded ribs and low thoracic-to-abdominal ratio and a bell-shaped chest (Fig. 19.13). Imaging may also reveal features of the underlying condition or commonly associated complications. Pulmonary hypoplasia is not uncommonly complicated by air leaks, such as pneumothorax. The pathologic criteria for the diagnosis of pulmonary hypoplasia are relatively well established and usually include an assessment of lung weight to body weight ratio and radial alveolar count.[219] Ratios greater than 0.018 suggest that pulmonary hypoplasia is unlikely, whereas a ratio of <0.012

suggests likely or probable pulmonary hypoplasia and need for further confirmation of the diagnosis. In cases with low lung weight to body weight ratio, the diagnosis is confirmed if the radial alveolar count is <75% of the mean normal value for GA.

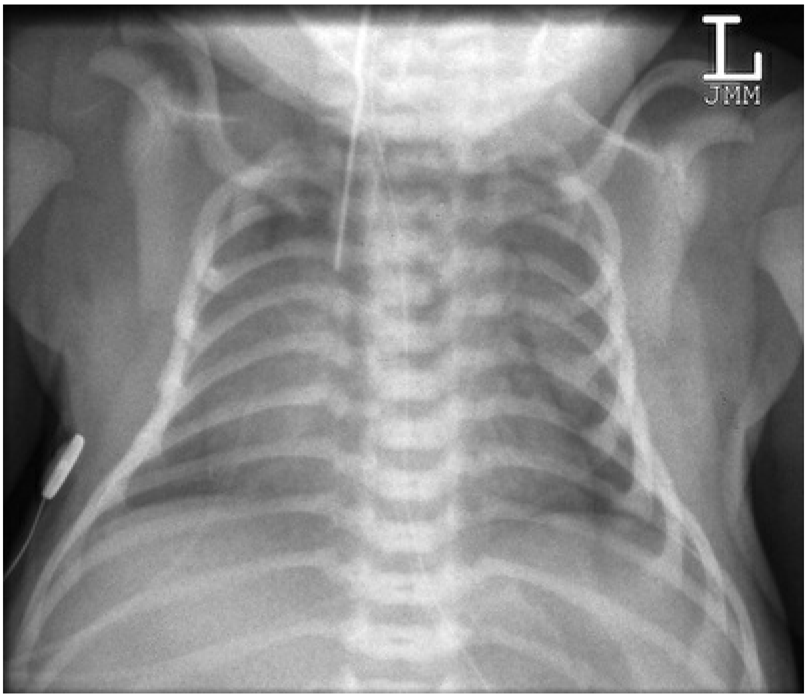

**FIG. 19.13** Pulmonary hypoplasia: chest x-ray demonstrates bell-shaped chest with low lung volumes. Severe lung hypoplasia due to prolonged oligohydramnios may be incompatible with successful gas exchange.

## Management

Severely affected infants have small lungs with poor compliance, oxygenation failure, and high ventilatory requirements. There is a substantial risk of air leaks, and thus some experts suggest low-pressure fast-rate ventilation or HFOV.[229] In cases with pulmonary hypertension, pulmonary vasodilators such as iNO should be considered.[230] Some infants may need home oxygen therapy for several months after discharge, and, in view of the considerable risk of respiratory exacerbations, annual influenza vaccine, pneumococcal vaccine, RSV prophylaxis, and stringent infection control should be recommended. Lung development and growth should be facilitated by careful attention to nutrition.

## Prevention

Prevention of pulmonary hypoplasia is theoretically possible if the underlying cause has been detected sufficiently early during the antenatal period and if the condition is amenable to intervention. Examples of conditions that have been treated *in utero* include pleural effusions, congenital lung lesions, fetal urinary obstruction, and CDH.[231–234] *In utero* thoracoamniotic shunting can drain fetal pleural effusions and cystic lung lesions and have been associated with resolution of hydropic features, in infants presenting with hydrops fetalis, and improved survival.[231] There is currently insufficient evidence to support *in utero* surgical repair of CDH.[233] More recently, efforts have been made to investigate the potential of early fetal endoscopic tracheal occlusion by balloon with subsequent deflation and removal at 34 weeks GA.[234,235] This approach has seen some improvements in infant survival for those predicted to have severe CDH (lung to head ratio < 0.7).[236]

## Prognosis

The prognosis of infants with pulmonary hypoplasia can be very poor depending on severity, with estimated mortality of >90% in those associated with severe persistent oligohydramnios due to preterm prelabor rupture of membranes with onset <25 weeks GA.[219] Mortality improves when the underlying condition impacting on lung development occurs later during pregnancy (>25 weeks) and is of relatively short duration (<6 days) and if there are no other associated conditions, such as PPHN.[219,237,238] Long-term morbidity includes limb abnormalities (incidence 27%–80%) due to the compression if associated with oligohydramnios,[239] BPD and recurrent wheezy episodes,[240] and neurodevelopmental deficits (incidence 28% if associated with rupture of membranes before 26 weeks GA).[241]

# Patent Ductus Arteriosus

## Epidemiology

The incidence of PDA is inversely related to GA, with estimated incidences of <0.1% and 42% for term infants and extremely low-birth-weight infants, respectively.[242,243]

## Etiology

PDA is caused by a failure of the ductus arteriosus to close during the transition of the infant from a fetal to extrauterine circulation after birth.

## Pathogenesis

Gas exchange in the fetus occurs at the placenta rather than the lungs. Blood is therefore shunted from the right ventricle and pulmonary artery away from the lungs and directly to the aorta via the ductus arteriosus. After birth, functional closure of the ductus arteriosus occurs. In term infants the process is complete in 20% of cases by 24 hours, 82% by 48 hours, and 100% by 96 hours. In preterm infants >30 weeks GA, 8% close by 24 hours, 60% by 48 hours, and almost 100% by 96 hours.[244] In preterm infants, especially <30 weeks GA, there is decreased ductal sensitivity to oxygen, poor intrinsic tone of the ductal wall, and the balance of vasodilators to vasoconstrictors favor ductal patency. Ductal closure is therefore often delayed. Anatomic closure relies on changes that occur after functional closure is complete; ductal patency therefore prevents this process from taking place. Other factors that are associated with delayed ductal closure include thrombocytopenia, respiratory distress, and persistently low $PaO_2$.[244,245]

## Clinical Features

Clinical features of PDA typically arise because of hemodynamically significant left-to-right shunting of blood from the aorta to the pulmonary artery. In view of the relatively high pulmonary pressure of newborn infants, the chance of clinical features developing before normal functional closure of the ductus is very low. As the PVR decreases, left-to-right shunting through the PDA increases and signs of left heart failure may develop. Clinically the infant may exhibit a harsh systolic murmur best heard at the upper left sternal border, hyperdynamic precordial impulse, and bounding peripheral pulses with widened pulse pressure. As the left-to-right pressure gradient increases, the murmur may become continuous. With worsening of the heart failure, the infant will develop increasing tachycardia, tachypnea, cardiomegaly, and hepatomegaly. The chest radiograph illustrates cardiomegaly, pulmonary plethora, and a wide angle between the left and right main bronchi due to left atrial dilation (Fig. 19.14). Particularly in preterm infants, the increased pulmonary blood flow could lead to pulmonary congestion and decreased pulmonary compliance. These infants may exhibit increasing oxygen and ventilatory requirements. Echocardiography is the gold standard for diagnosing PDA. In general, the PDA can be visualized by echocardiography in the parasternal short-axis view as a third branch of the main pulmonary artery alongside the left and right branch pulmonary arteries. Color Doppler could help to determine whether the flow through the PDA is left to right, right to left, or bidirectional. Additional features of a moderate to large left-to-right ductal shunt are bowing of the interatrial septum to the right with enlargement of the left atrium and ventricle. Left atrial enlargement with a left atrial to aortic root (LA:Ao) ratio > 1.4 : 1[245] is considered hemodynamically significant. The PDA size can be determined from the ductal size on color Doppler examination. If the shunt is large, flow reversal will be throughout diastole. Echocardiography is helpful to exclude other possible congenital cardiac abnormalities.

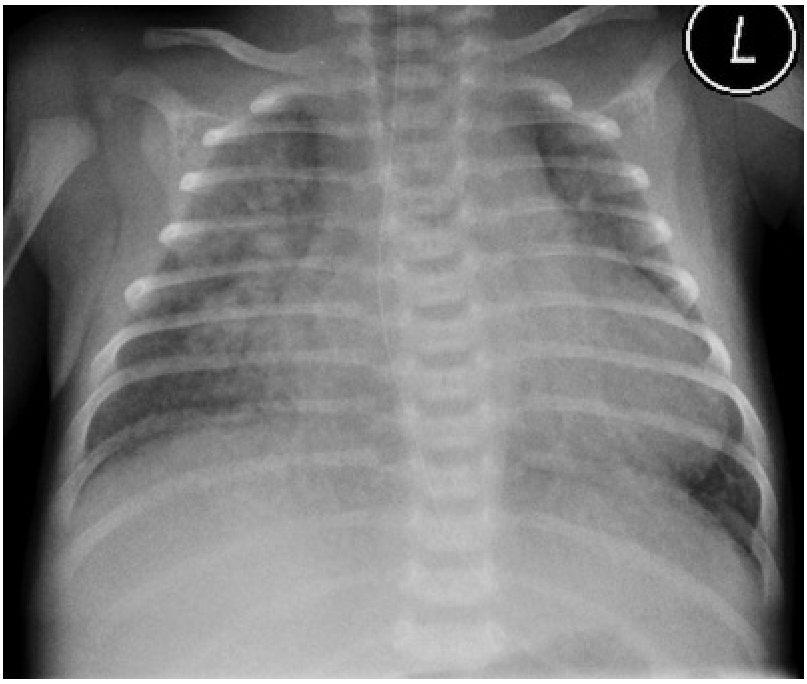

**FIG. 19.14** Patent ductus arteriosus: left-to-right shunting through the patent ductus arteriosus can lead to signs of congestive heart failure, including chest x-ray findings of cardiomegaly, pulmonary vessel congestion, and diffuse haziness.

## Prevention

In a meta-analysis,[246] PDA prophylaxis with ibuprofen showed reduced PDA incidence and need for rescue therapy/surgical closure but no improvement in any other short-term outcomes. In a randomized study, use of ibuprofen as PDA prevention showed a trend towards decreased PVL but did not affect any other clinical outcome.[247] In summary, despite the availability of several ductal closure strategies, whether the intervention is medical[246,248] or surgical,[249] no long-term benefits in terms of outcomes such as BPD, neurodevelopment or mortality have been demonstrated. Nevertheless, avoiding factors that may increase risk of PDA, such as excessive fluids,[250] hypoxia, and sepsis, would be prudent.

## Management

Ductal closure occurs naturally, and the clinical impact of PDA on individual patients can vary greatly. As with PDA prevention, there is very little evidence of long-term benefit of treatment of PDA.[251] It has therefore been controversial when, whom, and even whether to treat.[251,252] PDA spontaneously closes in a small proportion of extremely preterm infants (approximately 24%) and is more likely to be refractory to treatment.[253] Initial management of PDA in a preterm infant includes fluid restriction and diuretics. Cyclo-oxygenase inhibitors are the most commonly used drugs for ductal closure in preterm infants. Nonsteroidal antiinflammatory drugs (NSAIDs) such as indomethacin and ibuprofen are nonselective cyclo-oxygenase inhibitors which reduce the synthesis of prostaglandin E and thus shift the balance toward ductal closure. Indomethacin was previously the drug of choice; however, in recent studies, ibuprofen has been shown to be as effective in terms of ductal closure but associated with fewer side effects, such as transient renal impairment and NEC.[254] Ibuprofen is usually given as a 3-day course at 10 mg/kg on the first day, 5 mg/kg on the second day, and 5 mg/kg on the third day; however, there are small studies that report that higher doses may be more effective with no increase in side effects.[255] Side effects are increased with concomitant use of other drugs such as diuretics and corticosteroids. Use of diuretics in conjunction with indomethacin for the treatment of PDA did not improve urine output but increased serum creatinine and hyponatremia.[256] It has also been shown that concurrent use of NSAIDs and corticosteroids increases the risk of gastrointestinal perforation 10-fold.[257] Increasingly, paracetamol (acetaminophen) has been used as an alternative therapeutic option for treatment of PDA.[258] Meta-analyses suggest that paracetamol is as effective as ibuprofen for ductal closure.[259] However, maternal use of paracetamol during pregnancy has been associated with neurodevelopmental disorders in children,[260] and before more definitely long-term outcome data are available, use of paracetamol for ductal closure cannot be considered first-line therapy. Medical treatment by administration of the drugs via the oral route has been suggested to be feasible,[261,262] especially for countries with limited access to IV forms of ibuprofen, indomethacin, and paracetamol. Treatment failure is more common in infants with sepsis and extremely preterm infants.[263] Even for those infants with hemodynamically significant PDA, there is currently insufficient evidence to conclude whether surgical ligation or medical ductal closure is preferable as first-line treatment. Although surgery offers decreased closure failure rate, there is an increased risk of pneumothorax and retinopathy of prematurity.[264] Furthermore, despite surgical closure, infants may still go on to develop BPD.[265] Many neonatal units reserve surgical closure for infants with hemodynamically significant PDA refractory to treatment or when medical therapy is contraindicated. However, there is evidence that even in these infants, a nonintervention approach despite failure of medical closure may be associated with decreased incidence of BPD without increase in risk of NEC or IVH.[266] The question of management ultimately rests on clinical judgment on whether the PDA is hemodynamically significant with a trend towards conservative management in those who remain "asymptomatic."

## Prognosis

Complications associated with hemodynamically significant PDA include heart failure, BPD, neurodevelopmental impairment, NEC, and increased mortality.[267] The complications associated with both medical and surgical therapeutic options are substantial, and optimizing outcomes for an affected infant involves a balance of the risks of treatment versus the potential risks of the PDA. Objective, validated assessment tools to determine the hemodynamic significance of a PDA to an individual infant could potentially help to solve the difficult clinical problem of whether to intervene.

# Pulmonary Edema

## Epidemiology

Although there are very little data on the epidemiology of neonatal pulmonary edema, it is a well-known association of several common neonatal conditions.

## Etiology

Pulmonary edema is associated with several cardiopulmonary conditions, including TTN, perinatal asphyxia, left ventricular failure, RDS, hemodynamically significant PDA, and inflammatory pulmonary conditions.[268,269]

## Pathogenesis

Pulmonary edema occurs because of abnormal leakage of fluid from pulmonary capillaries into the lung parenchyma and alveolar spaces. This occurs when the pulmonary capillary pressure exceeds the plasma oncotic pressure or when there is disruption of the respiratory membrane. Pulmonary capillary pressure is increased in conditions with pulmonary congestion secondary to left ventricular dysfunction or fluid overload. Abnormalities of the pulmonary lymphatics can also lead to accumulation of fluid in the lungs. Plasma oncotic pressure can be decreased in hypoproteinemia, which is common in preterm infants and when inappropriately large volumes of crystalloids have been infused into the infant. The integrity of the respiratory membrane can be disrupted in many conditions, especially those associated with inflammatory or hypoxic insults. High ventilator settings can also cause excessive stretching of the alveoli and subsequent epithelial protein leaks.[268] In addition, epithelial ion transport plays an important role in lung lumen fluid clearance (see earlier section on pulmonary lung fluid clearance) and may offer new strategies for managing this condition.[270]

## Clinical Features

Newborn infants with pulmonary edema present with signs of respiratory distress and may exhibit tachycardia, tachypnea, and other signs related to the underlying condition. Chest radiograph features of pulmonary edema include increased vascular markings, perihilar shadowing (Fig. 19.15), linear septal opacities (Kerley B lines) in the lower lung fields, linear opacities along the horizontal and oblique fissures, cardiomegaly, and hazy lung fields. Investigations to determine the underlying cause should also be considered, such as echocardiography for cardiac causes. Lung ultrasonography may be helpful for detecting pulmonary edema, especially in cases in which the chest radiograph is indeterminate.[269]

Important differential diagnoses that may also coexist with pulmonary edema include pneumonia, RDS, and MAS.

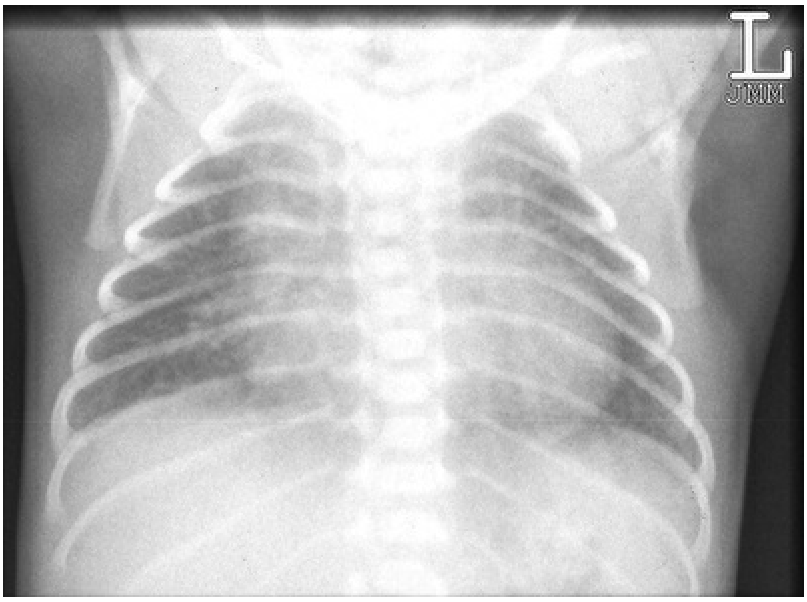

**FIG. 19.15** Pulmonary edema: increased vascular markings and linear septal opacities (Kerley B lines).

## Management

Fluid restriction, administration of diuretics, appropriate ventilatory support, and treatment of the underlying condition are the cornerstones of the management of pulmonary edema. Some investigators have shown that corticosteroids can upregulate epithelial ion transporters, which explains why antenatal and postnatal corticosteroids have been found to be helpful in conditions that are associated with pulmonary edema.[270]

## Prevention

The risk of neonatal pulmonary edema can be decreased by management strategies that decrease pulmonary congestion, increase plasma oncotic pressure, and minimize lung injury. Avoidance of excessive fluid administration and reduction of ventilator pressures may be helpful.

## Prognosis

Outcomes of pulmonary edema usually depend on the severity of the underlying condition, with excellent prognosis for self-limiting conditions such as TTN.

# Pulmonary Hemorrhage

## Epidemiology

Pulmonary hemorrhage has increased from 0.1% to 1.2% in the presurfactant era[271] up to 5.9%, according to a meta-analysis of surfactant trials.[272] However, its incidence may be underestimated because it has been reported to be the cause of death of 9% of newborns who underwent autopsy.[273]

## Etiology

Pulmonary hemorrhage has been shown to be associated with the presence of a hemodynamically significant PDA in preterm infants[274] and acute left ventricular failure due to asphyxia.[273] Other risk factors associated with increased risk of severe pulmonary hemorrhage include surfactant administration (especially if synthetic),[275] hypothermia, Rhesus hemolytic disease, and small for GA.[276]

## Pathogenesis

Analysis of hemorrhagic lung fluid from infants diagnosed with pulmonary hemorrhage revealed a relatively low Hct of only 10% and the presence of plasma proteins, suggesting that the fluid is composed of blood diluted with plasma filtrate.[273] It is believed that, although the hemorrhagic fluid appears to be bloody, it may be more appropriate to describe it as hemorrhagic pulmonary edema fluid. The association with acute left ventricular dysfunction suggests that pathogenesis of pulmonary hemorrhage is related to left-to-right shunting, pulmonary congestion, and pulmonary edema. Presence of clotting abnormalities[273] or hypoxic damage to the pulmonary capillaries also appears to play important roles in the pathogenesis.[271]

## Clinical Features

Infants who develop severe pulmonary hemorrhage often deteriorate suddenly on the first few days of life, with an earlier onset associated with more mature infants.[271] There is no standard definition of pulmonary hemorrhage but is usually recognized as the appearance of frank blood originating from the airway (usually seen in the ET tube) which is accompanied by acute clinical deterioration (e.g., increasing ventilator requirements and hemodynamic instability).[271,274] Pulmonary hemorrhage is usually associated with chest radiograph changes such as whiteout lung fields and air bronchograms (Fig. 19.16). Differential diagnoses include severe RDS, pneumonia, sepsis with disseminated intravascular coagulopathy, and airway injury.

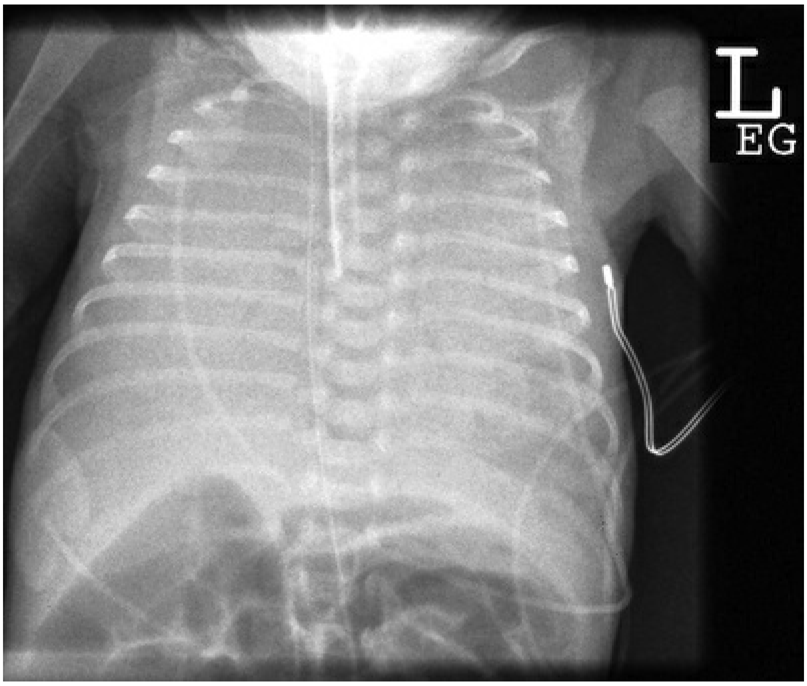

**FIG. 19.16** Pulmonary hemorrhage: diffuse bilateral opacification of the lungs, usually associated with blood in endotracheal secretions and clinical deterioration in oxygenation.

## Management

Conventional management of infants with severe pulmonary hemorrhage includes mechanical ventilation with high PEEP.[271,277] Heavy sedation and even paralysis is frequently used. Despite the association between surfactant use and pulmonary hemorrhage, it has been shown that a single dose of surfactant after the pulmonary hemorrhage has occurred may improve oxygenation.[278] In view of the clinical deterioration, broad-spectrum empirical antibiotics are usually commenced if not already in use. Anemia and coagulopathy should be corrected, with some authors suggesting the use of activated recombinant factor VII.[277] Management of associated heart failure should be considered. Some authors suggest that use of 4% cocaine (0.1 mL/kg, i.e., 4 mg/kg) or 1:10,000 epinephrine (0.1 mL/kg, i.e., 0.01 mg/kg or 0.5 mL, i.e., 0.05 mg) via the ET route may be helpful for short-term outcomes.[271,279]

## Prevention

Prophylactic indomethacin reduces the rate of early serious pulmonary hemorrhage, possibly because of its action on the PDA, but it is less effective in preventing severe pulmonary hemorrhage that occurs after the first week of life.[280] Judicious fluid management and prevention of heart failure may possibly decrease the risk of pulmonary hemorrhage.

## Prognosis

Mortality of severe pulmonary hemorrhage is high. Risk factors for higher mortality include early GA, lower birth weight, and small for GA.[271,280] The high ventilator settings and oxygenation failure often lead to long-term morbidity in survivors, including BPD and neurosensory impairment.

# Upper Airway Obstruction

## Epidemiology

Neonatal upper airway obstruction can occur at any level and reflect many different underlying conditions. The overall incidence of neonatal upper airway obstruction is unknown because the exact incidence of even laryngomalacia, one of the most common causes, remains unknown in the general population. It has been reported that the prevalence can range from 8% to 50% in infants with neuromuscular disease.[281] Rarer causes include choanal atresia, where the incidence is 1–2 per 10,000 live births.[282]

## Etiology and Pathogenesis

Causes associated with neonatal upper airway obstruction vary with the level of obstruction encountered. Examples include: choanal atresia, basal encephalocele (nasal); Pierre-Robin syndrome, Down syndrome, Crouzon syndrome (pharyngeal); laryngomalacia and vocal cord palsy (laryngeal).[283] The most common congenital cause of nasal obstruction is choanal atresia, which can occur in isolation or as part of a syndrome such as CHARGE (**C**oloboma of the iris and retina, **H**eart disease, **A**tresia choanae, **R**etarded growth, **G**enital hypoplasia, **E**ar defects) syndrome.[282] Obstruction at the pharyngeal level can occur from craniofacial anomalies. For example, if the tongue is too large (macroglossia) or the mandible is small (retrognathia/micrognathia), the base of the tongue can fall backwards, especially when the infant is in a supine position and it can obstruct the airway in the hypopharynx.[281] At the laryngeal level, causes of obstruction include structural lesions (e.g., laryngeal polyps/cysts) and functional causes (e.g., vocal cord palsy and laryngomalacia). Approximately 20% of vocal cord palsy is associated with injury to the recurrent laryngeal nerve caused by traction to the neck during delivery. Where vocal cord palsy is bilateral, neurologic causes should be sought. Other causes include surgical complications during ductal ligation or repair of tracheoesophageal fistula. In the neonate the epiglottis and the aryepiglottic folds can collapse upon the airway in laryngomalacia. In these cases, structural causes should also be sought because an associated airway lesion is seen in 18.9% and an associated cardiac lesion is present in as many as 31% of cases.[281]

## Clinical Features

Partial obstruction can vary in severity, and presenting features range from mild tachypnea or stridor to complete obstruction. Infants born with complete upper airway obstruction present immediately after birth with persistent cyanosis and ineffective respirations; they will remain refractory to conventional airway management measures[284] and can rapidly deteriorate with fatal consequences if not promptly treated.[285]

Infants with unilateral choanal atresia may not exhibit any clinical signs unless the unaffected side is blocked, at which point they may develop respiratory distress. The classical presentation of bilateral choanal atresia is respiratory distress at rest, which is absent when crying or mouth breathing. Differential diagnoses include choanal stenosis, nasal injury, and abnormal structures, (e.g., encephalocele or meningocele). Imaging by CT or MRI may be necessary to differentiate these causes.

Infants at risk of pharyngeal obstruction often present with dysmorphic features (e.g., retrognathia/micrognathia in Pierre-Robin syndrome, craniosynostosis and dysmorphic features in Crouzon syndrome, and characteristic facies in Down syndrome). Pharyngeal obstruction may produce stertor which is usually worse when the baby is nursed in a supine position. In cases in which it is unclear whether apneas are central or obstructive, infant polysomnography may be helpful to identify obstructive events.

Infants with laryngeal obstruction may present with stridor. One of the most common conditions causing laryngeal obstruction is laryngomalacia, which may present during the first 10 days of life. The stridor is usually worse with crying and feeding but improves when the infant is at rest. The severity of obstruction cannot be judged from the severity of the stridor, but rather from the presence of failure to thrive, respiratory distress, obstructive sleep apnea, and feeding difficulties.[281] Another commonly encountered example of airway obstruction is subglottic stenosis. This can be due to congenital structural abnormality but is more usually acquired secondary to intubation. Infants present with stridor or hoarseness after extubation with subsequent difficulty in intubation with the original sized tube. Vocal cord palsy can also present with stridor and hoarseness, and affected infants may also develop signs of aspiration pneumonia in view of the increased risk of aspiration. It may be life-threatening if both vocal cords are affected. Most causes of laryngeal obstruction can be diagnosed endoscopically, so a newborn presenting with stridor should undergo laryngoscopy and/or bronchoscopy to identify dynamic lesions. For extrinsic structural lesions, imaging by CT or MRI should be considered.

## Management

Nasal causes of obstruction can be relieved by an appropriately sized oropharyngeal airway. Choanal atresia requires surgical intervention to correct the occlusion. For cases with pharyngeal obstruction, some may respond to prone positioning. In the prone position, the base of the tongue can fall forwards and relieve obstruction of the pharyngeal airway. Oropharyngeal or nasopharyngeal airways may be helpful, but ET intubation or tracheostomy may be required in more severe cases.

In the absence of associated structural obstructive lesions, many of the common causes of laryngeal obstruction may resolve with expectant management. For example, laryngomalacia usually resolves by the age of 18–24 months,[281] whereas unilateral vocal cord palsy may resolve within weeks after resolution of the underlying cause.[286] If there are no signs of severe disease, conservative management is recommended. For those with substantial risk of life-threatening airway obstruction (e.g., bilateral vocal cord palsy), the infant may require ET intubation or tracheostomy. For infants with subglottic stenosis secondary to ET intubation, preextubation corticosteroids may be useful. Surgical intervention may be indicated in cases with severe disease (e.g., failure to thrive) and respiratory compromise.

## Prevention

The occurrence of acquired subglottic stenosis is associated with ET intubation. Minimizing the use of intubation and invasive ventilation by increasing the use of noninvasive ventilation may help to prevent subglottic stenosis. There are no effective means to prevent the other causes of upper airway obstruction.

## Prognosis

Mortality of upper airway obstruction can be high if complete or critical airway obstruction is present. However, this is relatively uncommon. The more common forms of obstruction, such as laryngomalacia and unilateral vocal cord palsy, are often mild and resolve without specific intervention.

# Gastroesophageal Reflux

GER is common in preterm infants, but its correlation with respiratory issues and apnea are small. Reflux of fluid up the esophagus will cause a reflexive closure of the vocal cords to protect the airway and may cause obstructive apnea until the infant is able to swallow the fluid. Inability to successfully close the larynx during GER can lead to recurrent aspiration pneumonia (discussed earlier in the chapter). Apnea may also trigger GER because the lower esophageal sphincter pressure decreases when hypoxia occurs.[287] Using a combination of esophageal impedance probes, pH probes, and respiratory monitors, it was demonstrated that approximately 3% of respiratory events/apneas followed a GER, whereas GER occurred in 9% of infants after an apnea event.[288] The GER events are associated with the clinical symptoms of apnea/bradycardia approximately 10% of time in term and preterm infants.[289] Aspiration of gastric secretions should be suspected in neonates with recurrent respiratory problems, especially if there is right upper lobe collapse or consolidation on the chest radiograph. Significant levels of fat-laden macrophages or pepsin have been shown in the tracheobronchial secretions of infants who are fed and have clinical features of aspiration; however, the diagnostic utilities are not high enough for these methods to diagnose aspiration as a standalone test.[290,291] The extent of reflux can be assessed using contrast and fluoroscopy in an upper gastrointestinal study, through pH or impedance monitoring, or through visualization of edema and irritation at the vocal cords. Even when GER is documented, there are still questions about the benefits of treatment.

## Management

Up to 25% of extremely preterm infant are discharged home on medications for GER, usually due to a belief that it helps with apnea.[287,292] According to recent surveys, more than 70% of these infants were started on medications for GER and apnea without any investigations.[287] Most neonatologists stop the medications when the infants are apnea free and greater than 36 weeks GA. Gastric acid suppressors, H2 blockers and proton pump inhibitors, are more commonly used than motility promoting agents (erythromycin, cisapride, metoclopramide). Randomized trials of proton pump inhibitors have not shown a benefit for GER and apnea but have shown increased adverse events. There is an association of acid-blocking agents with increased risk of NEC and sepsis, especially with gram-negative bacteria.[293] Routine use of medications to treat GER should be avoided in preterm infants. Promotility agents have had limited success in treating GER in preterm and term infants.[294] Erythromycin has had the most success; however, the risk of hypertrophic pyloric stenosis should be balanced against the potential benefits, especially during the first 2 weeks of life.[295] Thickening agents have not been shown to decrease symptoms of GER, and one was removed from the market because of an increased risk of NEC. Continuous feeds or transpyloric feedings have also not been shown to decrease apnea or GER.[294] Nissen fundoplication may be necessary in some infants with severe GER, as documented by upper gastrointestinal (GI) tract contrast studies, and signs of aspiration pneumonia.

# Bronchopulmonary Dysplasia

*Laurie Sherlock MD, Steven H. Abman MD*

## Introduction

Improved survival of very immature infants has contributed to an increase in the number of infants who develop bronchopulmonary dysplasia (BPD). BPD is a chronic lung disease that occurs in roughly 10,000–15,000 infants per year in the United States alone. This has important implications for the utilization of health resources, as follow-up studies have demonstrated that BPD infants require frequent readmission to the hospital in the first 2 years after birth for respiratory infections, asthma, and related problems; they also have persistent lung function abnormalities as adolescents and young adults. BPD most commonly occurs in prematurely born infants who have required mechanical ventilation (MV) and oxygen therapy for acute respiratory distress,[1–3] but it also can occur in immature infants who have had minimal initial lung disease.[4–6] Although BPD is most commonly associated with premature birth, it can occur in term or near-term infants due to severe acute lung injury, as reflected by a need for high mechanical ventilator support or extracorporeal membrane oxygenation (ECMO) therapy.

Over the past 40 years, the introduction of prenatal steroid use, surfactant therapy, new ventilator strategies, aggressive use of early continuous positive airway pressure (CPAP), changes in approach to managing patent ductus arteriosus (PDA), improved nutrition and other treatments have resulted in dramatic changes in the clinical course and outcomes of premature newborns with respiratory distress syndrome (RDS). Whereas the overall incidence of BPD has not declined over the past decade,[6] its severity has been clearly modulated by changes in clinical practice. There is now growing recognition that infants with chronic lung disease after premature birth have a different clinical course and pathology than had been traditionally observed in infants who were dying with BPD during the presurfactant era (Fig. 20.1).[4–8] The classic progressive stages with prominent fibroproliferation that first characterized BPD are often absent, and the disease has changed to being predominantly defined by a disruption of distal lung growth; this has been termed "the new BPD."[4] In contrast to classic BPD, the new BPD develops in preterm newborns who may have required minimal or even no ventilatory support and relatively low inspired oxygen concentrations during the early postnatal days (Fig. 20.2).[5,6] At autopsy, the lung histology of infants who die with the new BPD displays more uniform and milder regions of injury, but impaired alveolar and vascular growth remain prominent (Table 20.1). The implications of how these changes in BPD alter long-term pulmonary outcomes remain unknown. The new BPD is likely the result of disrupted antenatal and postnatal lung growth that leads to persistent abnormalities of lung architecture. It is unclear whether such infants subsequently experience sufficient catch-up lung growth to achieve and sustain improved lung function over time. To date, there are limited safe and effective preventative therapies for BPD, but there are promising new therapies directed either at reducing lung injury or improving lung growth.

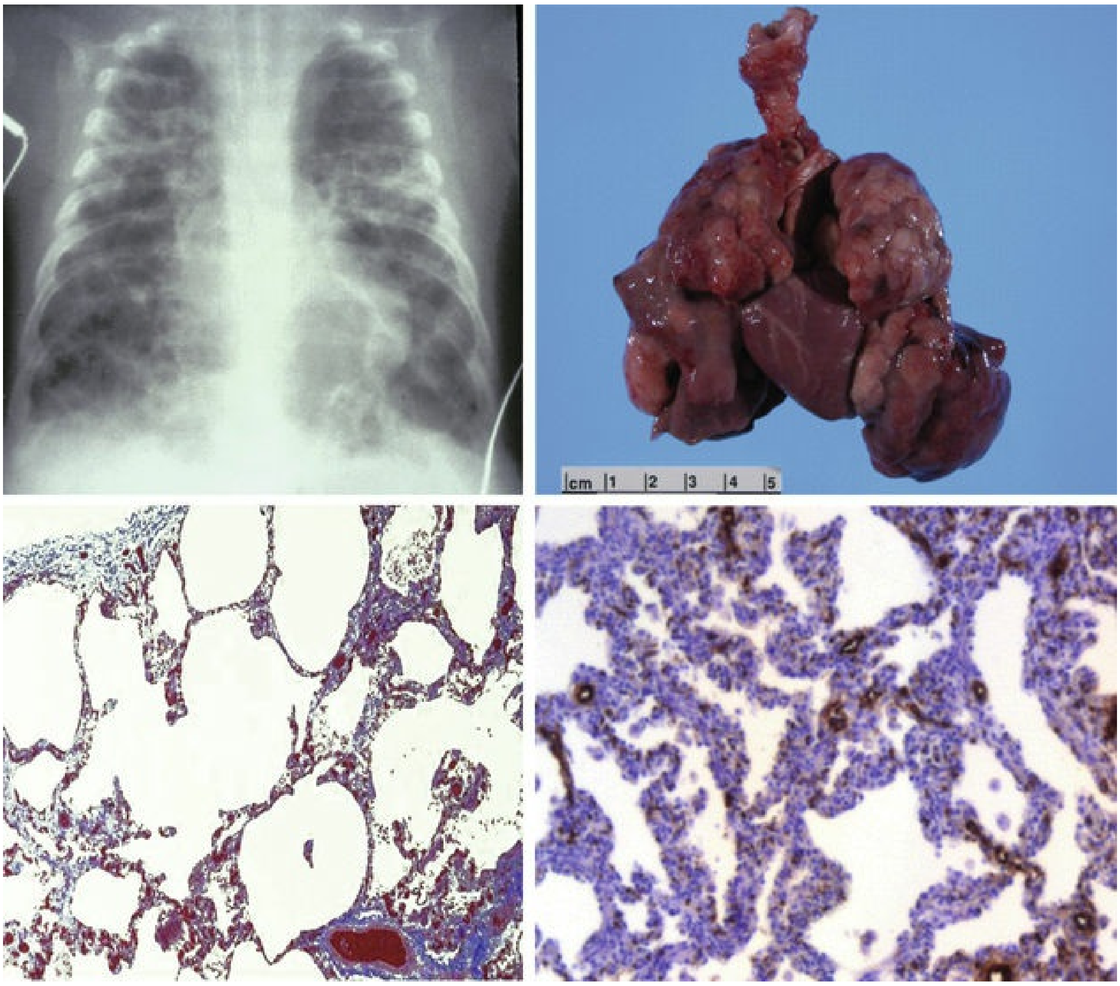

**FIG. 20.1** Radiographic, anatomic, and histologic features of severe bronchopulmonary dysplasia (BPD). Upper left panel shows a chest radiograph with hyperinflation, diffuse but patchy parenchymal infiltrate and cor pulmonale. Upper right panel shows gross appearance of severe fibroproliferative BPD. Note the cobblestone pattern with pseudofissures. Lower left panel shows marked alveolar simplification in an older child who died from a nonrespiratory cause. Lower right panel shows immunostaining for factor VIII to highlight a dysmorphic and simplified vascular bed.

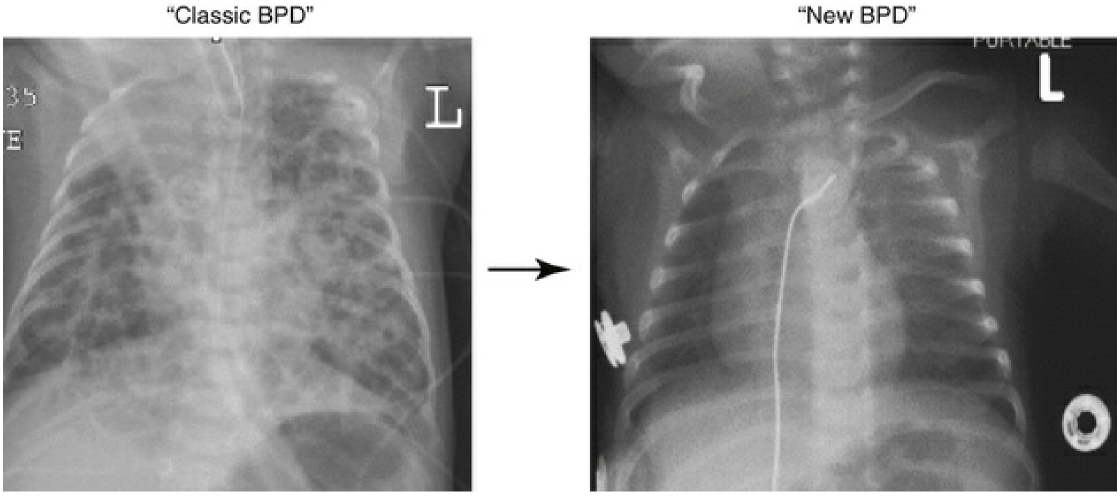

**FIG. 20.2** Chest radiographs illustrating the transition from severe bronchopulmonary dysplasia (BPD; Northway stage IV) in the presurfactant era (classic BPD) compared with a typical x-ray pattern from the new BPD.

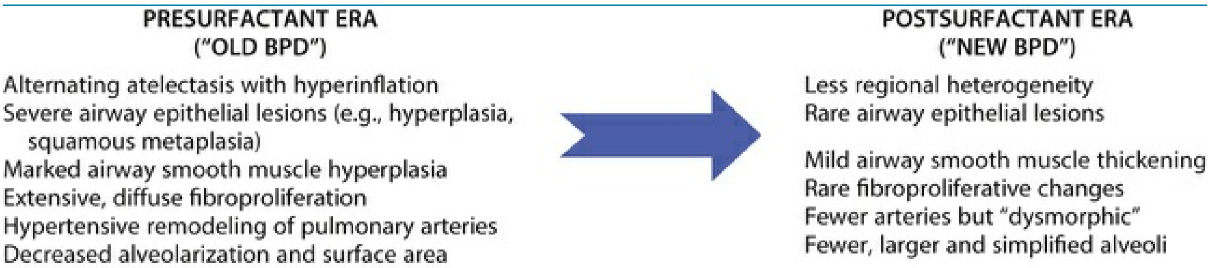
**Table 20.1**

### Changing Pathologic Features of Bronchopulmonary Dysplasia



| PRESURFACTANT ERA ("OLD BPD") | POSTSURFACTANT ERA ("NEW BPD") |
|---|---|
| Alternating atelectasis with hyperinflation | Less regional heterogeneity |
| Severe airway epithelial lesions (e.g., hyperplasia, squamous metaplasia) | Rare airway epithelial lesions |
| Marked airway smooth muscle hyperplasia | Mild airway smooth muscle thickening |
| Extensive, diffuse fibroproliferation | Rare fibroproliferative changes |
| Hypertensive remodeling of pulmonary arteries | Fewer arteries but "dysmorphic" |
| Decreased alveolarization and surface area | Fewer, larger and simplified alveoli |

*BPD,* Bronchopulmonary dysplasia.

Overall, BPD may perhaps be best considered as a "syndrome" rather than a single disease because etiologies, clinical course and respiratory outcomes are diverse and modulated by therapeutic interventions. The changing nature of BPD suggests that a standard binomial definition will not adequately predict long-term pulmonary outcomes. Importantly, there is growing recognition that prematurity itself, even in the absence of BPD and even in late preterm infants, is associated with significant late respiratory morbidity.[9–12] Additionally, there is a growing appreciation that interventions designed to prevent BPD should focus on late pulmonary and neurodevelopmental outcomes that have the most impact on the health and welfare of prematurely born children and their families rather than short-term outcomes (e.g., supplemental oxygen requirement at 36 weeks corrected age). Such a change in thinking about BPD requires the development of multidisciplinary teams of health care professionals and clinician-scientists, an appreciation of the magnitude, nature and chronic manifestations of prematurity and BPD and novel programs that provide continuity of long-term care. This chapter reviews the epidemiology, pathophysiology, and long-term outcomes of infants with BPD.

# Definition

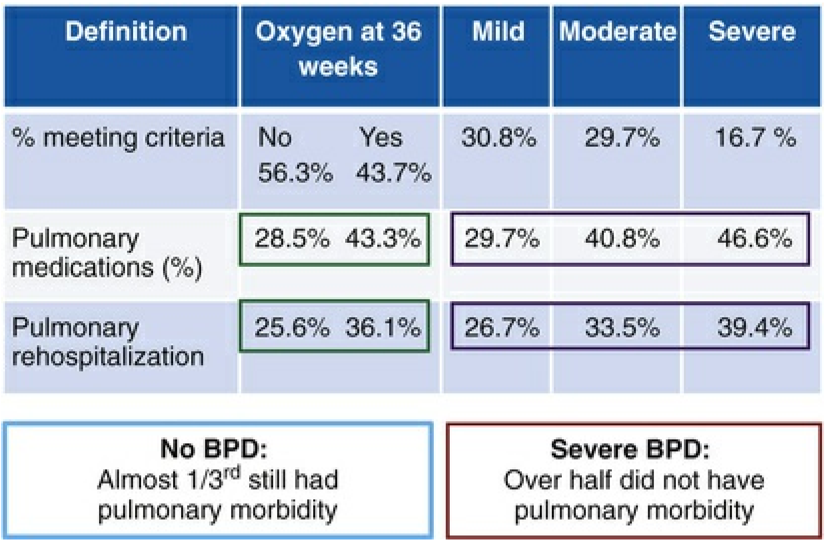
Despite extensive studies of premature infants with chronic lung disease, the definition of BPD remains problematic. Northway's initial diagnosis incorporated a clinical assessment, radiologic findings, and histopathology. Today current definitions of BPD diagnose the disease based on the treatment: oxygen requirement at 28 days or 36 weeks corrected gestational age. Ideally a diagnosis of BPD would act as an accurate surrogate to predict long-term pulmonary morbidity, would be a meaningful outcome measure for evaluating prevention and therapeutic interventions and would be consistently defined between units so it could be used to compare performance and identify best practices, identifying quality improvement measures and targeting future investigation. Unfortunately the current definition falls short on all counts. Owing to inconsistencies in how different institutes were defining BPD, a National Institutes of Health–sponsored conference developed a new definition of BPD that incorporates several components of previous definitions and adds a BPD severity categorization according to the level of respiratory support required at 36 weeks corrected gestational age or at the time of discgharge (Table 20.2).[13] The potential advantage of this approach is that BPD is defined as a spectrum of disease with early markers that may be predictive of long-term pulmonary morbidity. However, even with the improved current definition, sensitivity and specificity are lacking in predicting long-term pulmonary adverse outcomes. In one study evaluating pulmonary outcomes with different definitions of BPD, even with the improved definition, 20%–27% of very low birth weight (VLBW) neonates without a diagnosis of BPD still had long-term pulmonary morbidity requiring respiratory medications or rehospitalization for respiratory etiology.[14] For the VLWB neonates with a diagnosis of severe BPD, up to 50% did not have any long-term pulmonary morbidities (Fig. 20.3).[14]

**Table 20.2**

**National Institute of Health Consensus Conference: Diagnostic Criteria for Establishing Bronchopulmonary Dysplasia**

| Gestational Age | <32 Weeks | >32 Weeks |
|---|---|---|
| Time point of assessment | 36 weeks PMA or discharge, whichever comes first | >28 days but <56 days postnatal age or discharge, whichever comes first |
| | Treatment with oxygen >21% for at least 28 days | |
| Mild BPD | Breathing room air at 36 weeks PMA or discharge, whichever comes first | Breathing room air by 56 days postnatal or discharge, whichever comes first |
| Moderate BPD | Need for <30% $O_2$ at 36 weeks PMA or discharge, whichever comes first | Need for <30% $O_2$ to 56 days postnatal age or discharge, whichever comes first |
| Severe BPD | Need for >30% $O_2$ ± PPV or CPAP at 36 weeks PMA or discharge, whichever comes first | Need for >30% $O_2$ ± PPV or CPAP at 56 days postnatal age or discharge, whichever comes first |

*BPD,* Bronchopulmonary dysplasia, *CPAP,* continuous positive airway pressure; *PMA,* Postmenstrual age; *PPV,* positive pressure ventilation.



| Definition | Oxygen at 36 weeks | | Mild | Moderate | Severe |
|---|---|---|---|---|---|
| % meeting criteria | No<br>56.3% | Yes<br>43.7% | 30.8% | 29.7% | 16.7 % |
| Pulmonary medications (%) | 28.5% | 43.3% | 29.7% | 40.8% | 46.6% |
| Pulmonary rehospitalization | 25.6% | 36.1% | 26.7% | 33.5% | 39.4% |

**No BPD:**
Almost 1/3rd still had pulmonary morbidity

**Severe BPD:**
Over half did not have pulmonary morbidity

**FIG. 20.3** Current definitions of bronchopulmonary dysplasia (BPD) lack sensitivity and specificity to predict long-term pulmonary morbidities. (Modified from Ehrenkranz RA, Walsh MC, Vohr BR, et al. Validation of the National Institutes of

Health consensus definition of bronchopulmonary dysplasia. *Pediatrics*. 2005;116(6):1353-1360.)

An additional problem in defining BPD is the wide center-to-center variability in diagnosing the need for supplemental oxygen. A survey from the Vermont Oxford Network revealed striking variations in thresholds for instituting supplementary oxygen based on pulse oximetry, ranging from less than 84% to less than 96%, with only 41% of the respondents using the same criterion (<90%).[15] This alone has a marked impact on the reported incidence of BPD. For a given study population, the incidence of BPD decreased from 37% to 24% if the need for supplemental oxygen was defined by accepting oxygen saturations above 92% or 88% while breathing room air, respectively.[16] Use of an oxygen reduction test may better help to diagnose ongoing supplemental oxygen requirements.[16,17] Despite efforts to improve the diagnosis of BPD, the emerging practice trend of using of noninvasive positive pressure through heated high flow leaves up to 2.1% of infants unclassifiable with the current National Institute of Child Health and Human Development (NICHD) definition.[18] Further work is needed to identify early physiologic, structural, and genetic or biochemical markers of BPD that are predictive of critical long-term endpoints, such as the presence of late respiratory disease evidenced by recurrent hospitalizations, reactive airways disease, the need for prolonged oxygen, the need for respiratory medications or exercise intolerance during childhood.[19]

# Epidemiology

Pulmonary immaturity is the primary risk factor for BPD owing to incomplete structural and biochemical development, including inadequate surfactant, antioxidant, and antiprotease activities.[20] In the early 1960s, oxygen and MV were selectively used for premature infants with acute respiratory failure due to apnea and hyaline membrane disease. As these therapies were applied more widely, there was a growing recognition of premature infants who survived but developed chronic pulmonary disease with hypoxemia and chest radiographic abnormalities. In 1964, Shepard and colleagues reported that 50% of premature neonates who received oxygen and MV developed chronic lung disease.[21] In 1967, Northway and coworkers provided a comprehensive characterization of the clinical, radiologic and pathologic features of chronic lung disease in infants who had received high concentrations of oxygen and MV from birth.[1] On average, these premature infants were born at 34 weeks' gestation and weighed 2200 g, yet their mortality was 67%, and the surviving infants had persistent respiratory distress and abnormal chest radiographs beyond the first 4 weeks after birth. In the latter study, the term *bronchopulmonary dysplasia* was first applied, referring to the striking disruption of airway structure. This seminal study identified the interactive roles of three key pathogenic factors: lung immaturity, acute lung injury, and inadequate repair of the initial lung injury. This basic concept still provides an important paradigm for our current understanding of BPD.

Currently most infants who develop BPD are born with extreme prematurity, and 97% have birth weights below 1250 g.[22] The risk of BPD increases with decreasing gestational age, with an incidence of 85% for infants born at 22 weeks and 23% for those born at 28 weeks (Fig. 20.4).[7] It is also inversely associated with birth weight. The incidence has been reported to be as high as 85% in neonates between 500 and 699 g, but only 5% in infants with birth weights over 1500 g. Although the overall incidence of BPD is reported at about 20% of ventilated newborns, marked variability exists between centers.[23–26] This likely reflects regional differences in the clinical definitions of BPD, the number of infants born at the hospital versus born at outside facilities and transferred in, the proportion of newborns with extreme prematurity, and specific patient management. In the most immature infants, even minimal exposure to oxygen and MV may be sufficient to contribute to BPD. Two-thirds of infants who develop BPD have only mild respiratory distress at birth (Fig. 20.5).[6] Other observers have recognized this change in patterns of respiratory diseases[6,7] and have emphasized the importance of enhancing our understanding of the mechanisms of progressive respiratory deterioration and the lack of clinical improvement during the first week of life.

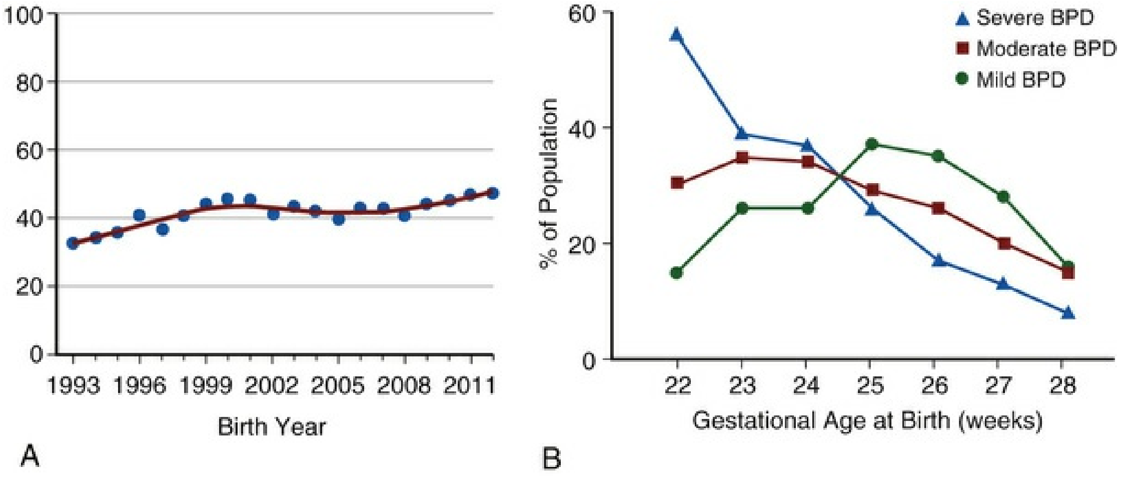


**FIG. 20.4** (A) The incidence of bronchopulmonary dysplasia (BPD) may be increasing. (B) Early gestational age is associated with increased BPD severity. (A, Modified from Stoll BJ, Hansen HI, Bell EF, et al. Trends in Care Practices, Morbidity, and Mortality of Extremely Preterm Neonates, 1993-2012. *JAMA*. 2015;314(10):1039-1051. B, Modified from Stoll BJ, Hansen NI, Bell EF, et al. Neonatal outcomes of extremely preterm infants from the NICHD Neonatal Research Network. *Pediatrics*. 2010;126(3):443-456.)

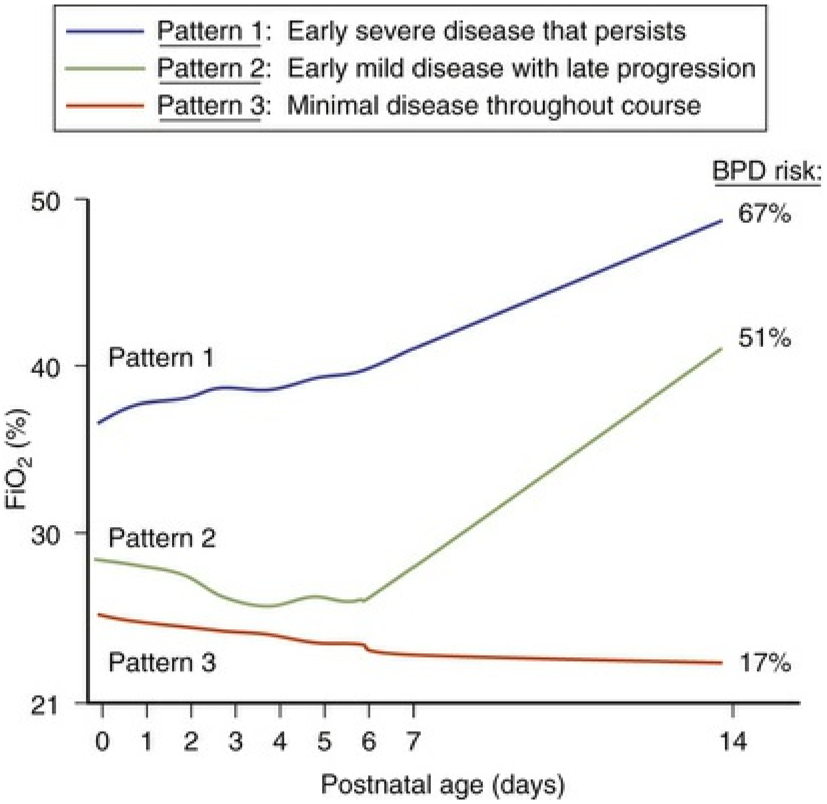

**FIG. 20.5** Changing patterns of respiratory disease with risk for bronchopulmonary dysplasia (BPD). (Modified

from Laughon M, Alfred EN, Bose C, et al. Patterns of respiratory distress during the first 2 postnatal weeks in extremely premature infants. *Pediatrics*. 2010;123:1124-1131.)

Despite advances in neonatal care, the incidence of BPD has not decreased; some reports suggest that it is actually increasing.[7] Whether this increase in incidence is a result of improved survival of the most immature and vulnerable infants is unclear. Whatever the case may be, it is a strong impetus to identify improved strategies for prevention and treatment.

# Etiology

Implications regarding the impact of extremely premature birth on lung growth and structure are best appreciated in the context of the stages of lung development (Fig. 20.6). The fetal lung at 24 weeks' gestation is generally at the late canalicular or early saccular stage of growth, which is characterized by immature airway structure, undifferentiated epithelial cells, a paucity of capillaries, and reduced surface area. Thus premature birth and injury at this early stage of development have profound implications for the risk of BPD, which provides additional challenges beyond those of premature birth at later stages of lung development.

**FIG. 20.6** Relationship between the stages of lung development, gestation and average birth of infants with classic bronchopulmonary dysplasia (BPD) versus the more extreme premature newborn that typifies the new BPD. (Modified from Laughon M, Alfred EN, Bose C, et al. Patterns of respiratory distress during the first 2 postnatal weeks in extremely premature infants. *Pediatrics*. 2010;123:1124-1131.)

Epidemiologic studies of BPD have identified many factors that modify the risk. Endogenous factors linked with BPD include gestational immaturity, lower birth weight, male sex, white or nonblack race, family history of asthma, and being small for gestational age.[27] Epidemiologic studies of BPD have yielded a number of predictive models.[28] Although none is routinely applied in caring for infants at risk of BPD, such models might serve as valuable tools for providing risk adjustment for clinical trials and other clinical research studies.

## Genetic Susceptibility

The risk for developing BPD is now recognized as being markedly influenced by complex interactions between genetic and environmental risk factors.[29] Variability in the incidence and severity of BPD among premature infants with similar environmental risk factors suggests that genetic susceptibility plays a critical role in the pathogenesis of BPD. Parker and colleagues first reported that genetic factors increase the risk for BPD in preterm twin pairs independent of birth weight, gestational age, gender, RDS severity, PDA, infection, antenatal steroids and other factors.[30] Lavoie and colleagues found that genetic effects accounted for about 80% of the observed variance in BPD susceptibility.[31] Initial genomewide association studies implicated SPOCK2 (SPARC/osteonectin, cwcv and kazal-like domains proteoglycan 2 gene) as significant in the development of BPD[32]; however, two subsequent genome wide association studies (GWAS) did not confirm this or find other genes to be significant.[33] Exome sequencing from newborn blood spot samples has identified numerous mutated genes in infants with BPD and could provide further insight into genetic risk moving forward.[34] Numerous genes are required for normal lung growth and development, and they are likely to contain sequence variations that modulate the risk for BPD. Published studies have identified several potential candidate genes, especially regarding surfactant proteins and cytokines.[35–38] However, many studies report small sample sizes, and the findings from most of the studies have not been replicated in subsequent cohorts. The current challenge is to specifically identify the candidate genes that contribute to the development of BPD and their interaction with the specific environmental stimuli that adversely affect lung injury, repair, and structure after preterm birth.

## Prenatal Factors

Recent studies have strongly implicated prenatal factors, including maternal smoking, preeclampsia, placental abnormalities, chorioamnionitis, and intrauterine growth restriction as key factors in the risk for BPD after preterm birth.[39–50] The interactions of prenatal and postnatal factors, such exposure to hyperoxia in growth-restricted infants or after exposure to endotoxin, may be critical factors as well. The question of how these epidemiologic observations are mechanistically linked with premature birth and poor respiratory outcomes is currently under intense laboratory and clinical investigation. Additional perinatal risk factors for BPD include absence of maternal glucocorticoid treatment and perinatal asphyxia.

## Postnatal Factors

BPD risk has also been linked with early neonatal influences, including lower Apgar scores, RDS, PDA,[51] higher weight-adjusted fluid intake,[52] earlier use of parenteral lipid, light-exposed parenteral nutrition, and duration of oxygen therapy. Among at-risk infants, the duration and approach to MV (including the use of high inspired oxygen, high peak inspiratory pressure, lower positive end-expiratory pressure, and higher ventilation rate) are also associated with BPD—relationships that could be causal or simply reflect the underlying severity of acute respiratory disease.[53–56] Increased BPD risk has been associated with hypocarbia (indicated by highest $PCO_2$ <40 at 48 or 96 hours), suggesting that aggressive ventilation can contribute to lung injury and BPD.[57] Colonization or infection with *Ureaplasma urealyticum*, postnatal cytomegalovirus infection and postnatal sepsis also appear to predispose to BPD.[58–60]

## Pathogenesis

Preterm infants are especially susceptible to injury caused by mechanical forces, oxidative stress, and inflammation due to the extreme structural and biochemical immaturity of the preterm lung. As Northway first observed, BPD has diverse, multifactorial etiologies, including hyperoxia, ventilator-induced lung injury (VILI), inflammation, and infection (Fig. 20.7).[1] Animal studies suggest that lung injury due to each of these adverse stimuli is at least partly mediated through increased oxidative stress, which further augments inflammation, promotes lung injury, and impairs growth factor–signaling pathways.

## Oxygen Toxicity

Oxygen toxicity due to high levels of supplemental oxygen markedly increases the production of reactive oxygen species (ROS), which overwhelm host antioxidant defense mechanisms in the immature lung and thus cause adverse molecular, biochemical, histologic, and anatomic effects.[1,61,62] Prematurely born infants are especially vulnerable to oxidative stress because their lungs are relatively deficient in antioxidant enzyme systems (e.g., superoxide dismutase, catalase and others) at birth. Early animal studies clearly demonstrated that high levels of supplemental oxygen promote lung inflammation, impair alveolar and vascular growth, and increase lung fibroproliferation. Experimentally, even relatively mild levels of hyperoxia may be sufficient to induce oxidative stress and impair growth of the immature lung.

A potential method for preventing the development of BPD appears to be prophylactic supplementation of human recombinant antioxidant enzymes.[63] In a multicenter randomized controlled trial (RCT), intratracheal treatment of premature infants at birth with recombinant human CuZn superoxide dismutase (rhSOD) was associated with fewer episodes of respiratory illness (i.e., wheezing, asthma, pulmonary infections) and less need for treatment with bronchodilators or corticosteroids at 1 year corrected age.[63,64] This suggests that rhSOD may prevent long-term pulmonary injury from ROS in high-risk premature infants. This trial failed to demonstrate a decrease in the diagnosis of BPD, highlighting the challenges posed by the current way in which BPD is defined. Further studies evaluating recombinant antioxidants enzymes have not yet been done.

## Ventilator-Induced Lung Injury

MV can induce injury through “volutrauma,” in which phasic stretch or overdistention of the lung can induce lung inflammation, permeability edema, and subsequent structural changes that mimic human BPD, even in the absence of high levels of supplemental oxygen.[65,66] Aggressive MV with hypocarbia has been associated with the development of BPD, as reports have shown an inverse relationship between low $PaCO_2$ levels and BPD development.[57] High tidal volumes should be avoided during MV and even during resuscitation in the delivery room.[67] In an experimental study demonstrating a relationship between the size of manual inflations and lung damage in lambs, adverse effects were demonstrated even with inflations of 8 mL/kg.[67–69] Although small tidal volumes may reduce the risk for VILI in preterm infants, failure to recruit and maintain adequate functional residual capacity (FRC), even with low tidal volumes, is injurious in experimental models.[69]

## Inflammation

Experimental and clinical studies have shown that inflammation clearly plays a central role in the pathobiology of BPD.[70–72] Oxygen toxicity, volutrauma, and infection can induce early and sustained inflammatory responses that promote the recruitment and activation of neutrophils, which persist in infants who develop BPD.[73] Levels of multiple proinflammatory cytokines (e.g., interleukins [ILs] such as IL-1β, IL-6 and soluble intracellular adhesion molecule 1 [ICAM-1]) and growth factors (e.g., transforming growth factor-β [TGR-β], vascular endothelial growth factor, and others) are present and altered in lung lavage and blood samples from premature infants who subsequently develop BPD versus controls.[71–73] IL-1β induces the release of inflammatory mediators, activating inflammatory cells and upregulating adhesion molecules on endothelial cells. ICAM-1 is a glycoprotein that promotes cell-to-cell contact. Direct contact between activated cells leads to further production of proinflammatory cytokines, such as IL-8, which induces neutrophil chemotaxis, inhibits surfactant synthesis and stimulates elastase release.[73] The levels of collagenase and phospholipase A2 are also increased, and oxidative modification results in the inactivation of alpha-1-antiprotease, which further tips the protease-antiprotease imbalance to favor injury. Lung inflammation is associated with loss of endothelial basement membrane and interstitial sulfated glycosaminoglycans,[74] which are important in inhibiting fibrosis. Tumor necrosis factor alpha (TNF-$\alpha$) and IL-6 induce fibroblast and collagen production.[70,75,76] Increased TGF-β and impaired vascular endothelial growth factor (VEGF) signaling have been strongly linked with the risk for BPD.[77–80] Leukotrienes are present at high levels in the lungs of infants developing BPD and remain elevated even at 6 months of age.[81,82]

Evidence that a systemic inflammatory response contributes to the pathogenesis of BPD led investigators to explore the contributions of antenatal, perinatal, and postnatal inflammation to lung injury.[83] Observational studies have suggested an association between amniotic fluid markers and placental and umbilical cord pathology of chorioamnionitis with BPD.[84,85] The combined effects of antenatal infection or inflammation and clinical factors might contribute to the occurrence of BPD via a number of mechanisms: direct injury of pulmonary parenchyma, disruption of the developmental milieu, impaired angiogenesis,[86,87] or activation (priming) of immune cells in the lung, thus provoking an exaggerated inflammatory injury in response to a variety of prenatal, perinatal, and postnatal insults.[83] BPD may be increased in infants whose mothers had chorioamnionitis.[49] This is because intraamniotic endotoxin exposure can disrupt alveolar and vascular development and thus lead to a decreased alveolar number and pulmonary hypertension (PH).[88] In a case-control study of 386 infants born at or below 1500 g (after adjusting for other BPD risk factors), chorioamnionitis alone appeared to be associated with reduced risk of BPD; however, chorioamnionitis followed by 7 days of MV or postnatal sepsis had a synergistic effect that substantially increased the risk of BPD.[89] These data suggest that chorioamnionitis might make the lung more susceptible to postnatal injury from a "second hit" of hyperoxia or ventilator-induced injury. Alternatively, these findings also suggest variable effects of chorioamnionitis on lung maturation versus arrested development, in which greater prenatal injury is reflected by an increased need for more ventilator and oxygen support.[88]

# Pathophysiology

## Respiratory Function

Nonuniform damage to the airways and distal lungs results in variable time constants for different areas of the lungs. Inspired gas may be distributed to relatively poorly perfused lung, thereby worsening ventilation-perfusion matching. Decreased lung compliance appears to correlate strongly with morphologic and radiographic changes in the lung. Dynamic lung compliance is markedly reduced in infants with established BPD, even in those who no longer require oxygen therapy.[90] The reduction in compliance is due to small airway narrowing, interstitial fibrosis, edema, and atelectasis. Established BPD is primarily characterized by reduced surface area and heterogeneous lung units in which regional variations in airway resistance and tissue compliance lead to highly variable time constants throughout the lung. As a result, MV of severe BPD, especially beyond the first few months of life, requires strikingly different ventilator strategies than commonly used earlier in the disease course (Fig. 20.8). Such strategies generally favor longer inspiratory times, larger tidal volumes, higher positive end-expiratory pressure (PEEP), and lower rates to allow more effective gas exchange and respiratory function.[91]

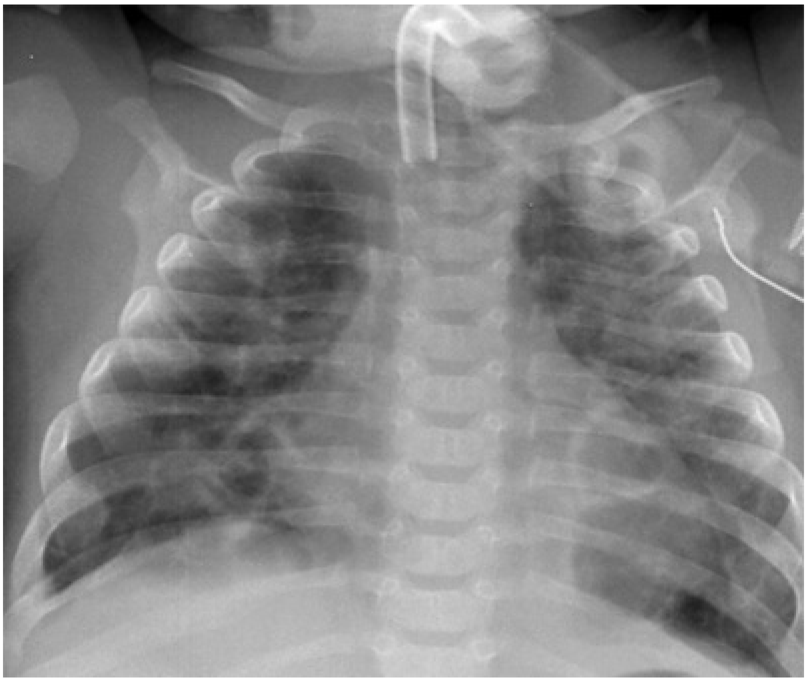

**FIG. 20.8** Chest radiograph of bronchopulmonary dysplasia in an infant with tracheostomy and chronic ventilation.

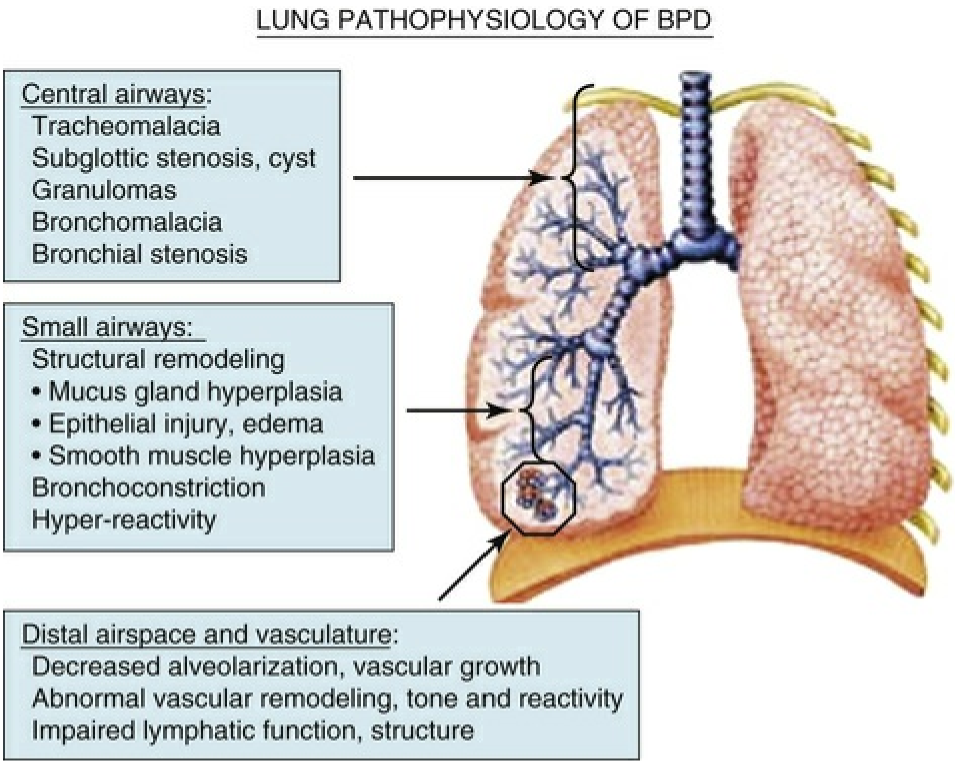
Although the new BPD has been characterized as an arrest of distal lung and vascular growth, most of these observations were based on lung histology; evidence that provided direct physiologic data to support this finding was lacking. Tepper and colleagues have demonstrated the important finding of reduced lung surface area in infants with BPD by utilizing novel methods of assessing diffusion capacity.[92] Their recent work provides in vivo evidence for impaired diffusion capacity secondary to both decreased alveolar surface area and decreased pulmonary capillary bed.[93]

## Pulmonary Circulation

Acute lung injury also impairs growth, structure, and function of the developing pulmonary circulation after premature birth.[94,95] Endothelial cells are particularly susceptible to oxidant injury due to hyperoxia or inflammation. The media of small pulmonary arteries may also undergo striking changes, including smooth muscle cell proliferation, precocious maturation of immature pericytes into mature smooth muscle cells, and incorporation of fibroblasts into the vessel wall and surrounding adventitia.[96] Structural changes in the lung vasculature contribute to high pulmonary vascular resistance (PVR) due to narrowing of the vessel diameter and decreased vascular compliance. Decreased angiogenesis may limit vascular surface area, causing further elevations of PVR, especially in response to high cardiac output with exercise or stress. The pulmonary circulation in BPD patients is further characterized by abnormal vasoreactivity, which also increases PVR (Fig. 20.9).[97] Abnormal pulmonary vasoreactivity is evidenced by a marked vasoconstrictor response to acute hypoxia.[98] Cardiac catheterization studies have shown that even mild hypoxia causes marked elevations in pulmonary arterial pressure, even in infants with modest basal levels of PH. Maintaining oxygen saturation levels above 92%–94% effectively lowers pulmonary arterial pressure.[97,98] Strategies to lower pulmonary arterial pressure or limit lung injury to the pulmonary vasculature may limit the subsequent development of PH in BPD.



LUNG PATHOPHYSIOLOGY OF BPD
Central airways:
Tracheomalacia
Subglottic stenosis, cyst
Granulomas
Bronchomalacia
Bronchial stenosis
Small airways:
Structural remodeling
• Mucus gland hyperplasia
• Epithelial injury, edema
• Smooth muscle hyperplasia
Bronchoconstriction
Hyper-reactivity
Distal airspace and vasculature:
Decreased alveolarization, vascular growth
Abnormal vascular remodeling, tone and reactivity
Impaired lymphatic function, structure

**FIG. 20.9** Lung pathophysiology of bronchopulmonary dysplasia.

Early injury to the lung circulation leads to the rapid development of PH, which contributes significantly to the morbidity and mortality of severe BPD.[99] Persistent echocardiographic evidence of PH beyond the first few months has been associated with up to 40% mortality in infants with BPD.[100] High mortality rates have been reported in infants with BPD and severe PH, especially in those who require prolonged ventilator support (Fig. 20.10).[101] Although PH is a marker of more advanced BPD, elevated PVR also causes poor right ventricular function, impaired cardiac output, limited oxygen delivery, increased pulmonary edema, and perhaps a higher risk for sudden death.

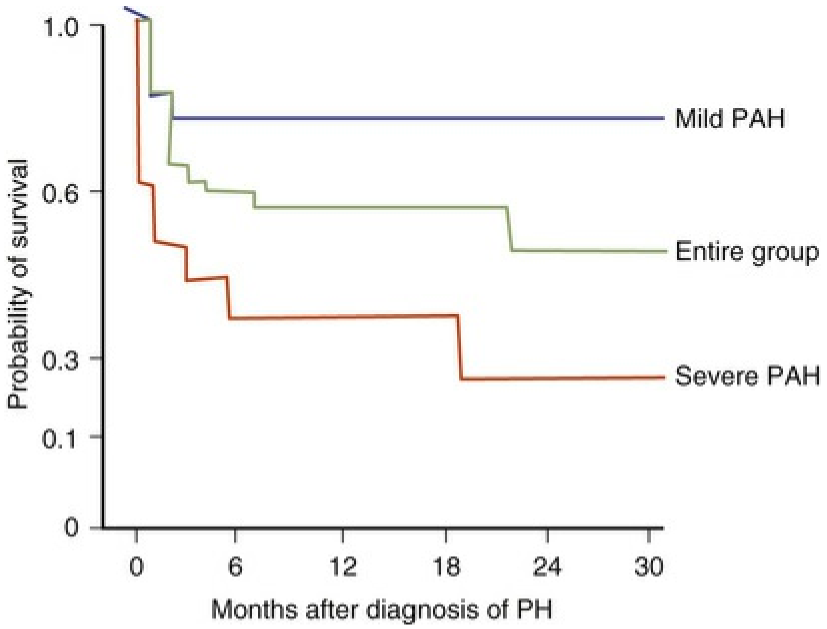


**FIG. 20.10** High mortality associated with late pulmonary arterial hypertension (PAH) in bronchopulmonary dysplasia. (Modified from Khemani E, McElhinney DB, Rhein L, et al. Pulmonary artery hypertension in formerly premature infants with bronchopulmonary dysplasia: clinical features and outcomes in the surfactant era. *Pediatrics*. 2007;120:1260-1269.)

In addition to the adverse effects of PH on the clinical course of infants with BPD, the lung circulation is further characterized by persistence of abnormal or “dysmorphic” growth, including a relative paucity of small pulmonary arteries with an altered pattern of distribution within the interstitium of the distal lung.[86,102] In infants with severe BPD, decreased vascular growth occurs in conjunction with marked reductions in the formation of alveoli, suggesting that the new BPD is primarily characterized by growth arrest of the developing lung. This reduction of alveolar-capillary surface area impairs gas exchange, thereby increasing the need for prolonged supplemental oxygen and ventilator therapy. This causes marked hypoxemia with acute respiratory infections and late exercise intolerance and further increases the risk for developing severe PH. Experimental studies have further shown that early injury to the developing lung can impair angiogenesis, which contributes to decreased alveolarization and simplification of distal lung airspace (the “vascular hypothesis”).[86] Thus, abnormalities of the lung circulation in BPD are related not only to the presence or absence of PH but also, more broadly, to *pulmonary* *vascular disease* after premature birth. This becomes manifest by decreased vascular growth and structure, thus also contributing to the pathogenesis and abnormal cardiopulmonary physiology of BPD.

Clinical studies have shown that the metabolic function of the pulmonary circulation is also impaired, as reflected by the lung's reduced clearance of circulating norepinephrine (NE).[103] Normally, 20%–40% of circulating NE is cleared during a single passage through the lung, but infants with severe BPD have an increase, suggesting a net production of NE across the pulmonary circulation. It is unknown whether impaired metabolic function of the lung contributes to the pathophysiology of BPD or is simply a marker of severe pulmonary vascular disease. It has been speculated that high catecholamine levels may lead to left ventricular hypertrophy (LVH) or systemic hypertension, known complications of BPD.

In addition to pulmonary vascular disease and right ventricular hypertrophy, other cardiovascular abnormalities associated with BPD include LVH, systemic hypertension, and the development of prominent systemic-to-pulmonary collateral vessels.[104,105] Infants with severe BPD can develop LVH in the absence of right ventricular hypertrophy. Left ventricular diastolic dysfunction can contribute to lung edema, diuretic dependency, and PH in some infants with BPD.[106]

Prominent bronchial or other systemic-to-pulmonary collateral vessels were noted in early morphometric studies of infants with BPD and can readily be identified in many infants during cardiac catheterization.[107,108] Although these collateral vessels are generally small, large collaterals may contribute to significant shunting of blood flow to the lung, resulting in edema and the need for higher levels of supplemental oxygen. Collateral vessels have been associated with high mortality in some patients with both severe BPD and PH. Some infants have improved after embolization of large collateral vessels, as reflected by a reduced need for supplemental oxygen, ventilator support, and diuretics. The contribution of collateral vessels to the pathophysiology of BPD, however, is poorly understood.

# Clinical Findings

## Physical Findings

Multiple abnormalities of lung structure and function contribute to late respiratory disease in BPD (see Fig. 20.5). Depending on the severity of BPD, findings on physical examination are variable and some infants may not have any abnormal findings. Chronic respiratory signs in children with BPD include tachypnea with shallow breathing, retractions, head bobbing, and a paradoxical breathing pattern. Auscultation may reveal coarse rhonchi, crackles, and wheezes. Some infants may demonstrate systemic hypertension during the first year of life. This systemic hypertension in BPD may be mild, transient, or striking. It usually responds to medication.[104,105] The etiology remains obscure, but further evaluation of some affected infants reveals significant renovascular or urinary tract disease.

## Imaging

Chest radiography is easily and frequently obtained in infants with BPD; however, its utility in diagnosis is limited owing to variable findings and the fact that many infants may have minimal radiologic abnormalities. Some patients may show lung fields with diffuse haziness. Patients with severe disease may demonstrate areas of hyperinflation and air trapping alternating with areas of fibrosis and atelectasis. Pulmonary edema may be present, especially during acute exacerbations.

Computed tomography (CT) of the chest has been used to identify structural abnormalities in patients with BPD, demonstrating increased airspace area reflecting alveolar simplification, hyperexpansion, emphysema, fibrosis and interstitial abnormalities, and mosaic attenuation.[109] Several different scoring systems have been developed correlating with the severity of BPD.[110] Longitudinal assessment by chest CT is not routinely used owing to concerns of exposing patients to large doses of ionizing radiation. New low-dose high-resolution CT protocols decrease this exposure, with dosing equivalent to 10–15 chest x-rays.[111] Nevertheless, the risk of serial radiation exposure limits the utility of this imaging modality.

Magnetic resonance imaging (MRI) of the lung is an alternative imaging modality without the risk of ionizing radiation; however, this is complicated, in that lungs have low proton density and alveolar spaces contribute to rapid signal decay, making imaging technically challenging. MRI with a hyperpolarized noble gas such as helium or xenon can improve sensitivity in identifying airway abnormalities. A proof-of-concept study demonstrated the safe performance of a nonsedated hyperpolarized-gas MRI in a healthy infant,[112] and this technique may facilitate longitudinal assessment of patients with BPD in the future.[113]

## Pulmonary Function Tests

Increased airway resistance can be demonstrated even during the first week after birth in preterm neonates at risk for BPD.[114] Infants with BPD at 28 days of age have an increased total respiratory and expiratory resistance with severe flow limitation, especially at low lung volumes.[115] The presence of tracheomalacia may also result in airflow limitation, which is worsened by bronchodilator therapy. In the early stages of BPD, the functional lung volume is often reduced due to atelectasis, but during later stages there is gas trapping with hyperinflation. The use of pulmonary function testing to follow the progression of BPD and the response to therapeutic interventions has increased but is still not commonly applied in the clinical setting.

## Laboratory Findings

There is no specific laboratory test for the diagnosis of BPD. Patients with BPD may demonstrate hypercarbia and elevated bicarbonate levels in compensation for respiratory acidosis. Although not routinely used in clinical practice, changes in cytokine profiles have been associated with the development of BPD.[72,73] Increased concentrations of IL-1β, IL-6, IL-8, IL-10, and interferon-γ and decreased concentrations of IL-17, RANTES (regulated on activation, normal T cell expressed and secreted), and TNF-β have been observed. A recent study identified markers of urinary inflammation and oxidative stress that are associated with an increased risk of developing BPD.[116] Increased 8-hydroxydeoxyguanosine levels, a marker of oxidative stress–derived DNA damage, were associated with increased BPD. Greenough and colleagues have shown increased exhaled nitric oxide on day of life (DOL) 28 is associated with increased risk of BPD.[117] Research continues to seek improved markers to predict or identify infants at risk for long-term pulmonary morbidities.

## Echocardiographic Findings

Routine echocardiograph monitoring is recommended at 36 weeks' corrected gestational age to assess for evidence of PH. Cardiac catheterization remains the gold standard for diagnosing PH. However, owing to its invasive nature, it is typically performed only in patients with severe disease. Tricuspid regurgitant jet velocity (TRJV) is used to estimate right ventricular systemic pressure (RVSP); however, other findings used to diagnose PH include right ventricular hypertrophy, right atrial enlargement, and interventricular septal flattening.[99]

# Prevention

As described earlier, diverse mechanisms contribute to the pathogenesis of BPD, which perhaps makes it less surprising that there is no single therapy or prevention strategy except for the prevention of premature birth. The use of antenatal steroids in mothers at high risk of delivering a premature infant has reduced the incidence of neonatal death and RDS by 50%[118] but failed to decrease the incidence of BPD, even in combination with postnatal surfactant. Thus far, there has been no clear advantage to one antenatal steroid dosing regimen.[119] Similarly, antenatal thyrotrophin-releasing hormone therapy did not reduce BPD in randomized trials.[120]

Postnatally prevention of BPD begins in the delivery room. Emerging evidence suggests that avoiding or limiting MV leads to a decreased incidence of BPD.[6,121–123] Rapid establishment of FRC has become an early goal for all VLBW infants in attempts to avoid MV. Use of a T-piece resuscitator as opposed to a self-inflating bag has been shown to decrease intubation rates.[124] Sustained lung inflation immediately after birth is being investigated as a strategy to establish FRC and avoid lung injury. One RCT demonstrated a decreased need for MV at 72 hours; yet there was no difference in BPD at 36 weeks and an increase in pneumothorax.[125] Results of a larger RCT are pending.[126]

There has been a practice trend supporting early and aggressive use of noninvasive ventilation to avoid MV in hopes of decreasing BPD.[127] Several RCTs have compared the use of early nasal continuous positive airway pressure (nCPAP) with intubation.[128–130] A meta-analysis of these results reveals a small but significant decrease in the incidence of BPD or death.[123] Additionally, early nCPAP reduced the need for subsequent intubation and was associated with a reduced rate of steroid prescription and shorter duration of ventilation.

Despite efforts to avoid intubation, 85% of infants born between 22 and 28 weeks are exposed to MV[15] and CPAP failure rates remains high, between 40% and 60%.[128–130] Although no optimal ventilation mode has emerged, it is clear from physiologic studies that tidal volumes and inspired oxygen concentrations should be reduced as low as possible to avoid hypocarbia, volutrauma, and oxygen toxicity and that lung recruitment strategies should be employed. The association of volutrauma with the development of BPD has led to the use of strategies such as permissive hypercapnia to minimize lung injury.[131] Despite the physiologic plausibility of permissive hypercapnia as a prevention strategy for BPD, the recent permissive hypercapnia in extremely low birthweight infants (PHELBI) trial did not show a difference in BPD or death between groups targeting high compared to low carbon dioxide, suggesting that more research is needed to better understand optimal early ventilator strategies.[132] Meta-analysis of randomized trials has demonstrated that patient-triggered ventilation does not reduce BPD; if started in the recovery phase of RDS, however, it significantly shortens weaning from MV.[133] The results of randomized trials of high-frequency oscillatory ventilation (HFOV) or high-frequency jet ventilation (HFJV) have been inconsistent.[134] Two large studies that incorporated prenatal steroid and surfactant replacement therapy yielded different results. In one study (which restricted entry to VLBW infants with moderate to severe hypoxemic respiratory failure following surfactant administration), there was a significant benefit from HFOV of higher survival without BPD.[135] No substantial benefit or adverse effects of HFOV were found in the other study, however, which randomized premature infants (younger than 29 weeks) within 1 hour of birth regardless of the degree of lung disease.[136] An explanation for those conflicting results may be that in the current era, in which modified conventional ventilation strategies are used, pulmonary benefit from HFOV may be demonstrable only in infants with moderate to severe disease. Clearly the strategy applied for either conventional or HFOV is more important than the device itself. HFOV is frequently used as "rescue" therapy in premature newborns with severe respiratory failure despite treatment with exogenous surfactant. Whether such an approach reduces BPD or improves long-term outcomes requires appropriate testing.

Exogenous surfactant therapy to treat RDS has changed the face of neonatology in the last century. Surfactant reduces the combined outcome of death and BPD but not BPD alone.[137] Arguably, this may be due to the increased survival of very immature infants at high risk of BPD. The "intubate, surfactant, extubate" (INSURE) technique was originally described in 1994, combining early surfactant administration with rapid extubation to minimize duration of MV.[138] This technique has been evaluated as both an early and a prophylactic intervention (within the first hour of life or in the delivery room) as well as a rescue technique once infants develop symptoms of RDS. A meta-analysis of early INSURE showed improved outcomes including decreased oxygen requirement at 28 days and less exposure to MV; however, there was no decrease in BPD or mortality.[137] Studies of late or rescue INSURE have had a small number of participants and more studies are needed to determine if this technique should be used broadly. Several groups are currently investigating techniques to deliver surfactant to spontaneously breathing infants while avoiding intubation altogether.[139–141] Ongoing multicenter RCTs are currently recruiting and hopefully will provide greater insight in the coming years.[142]

The use of late surfactant for preterm infants on prolonged MV and thus at high risk for BPD has been evaluated in two recent RCTs. Hascoet et al. showed that late surfactant administration did not decrease the incidence of BPD; however, it did decrease long-term pulmonary morbidities including rehospitalization for respiratory illnesses and need for chest physiotherapy.[143] Ballard et al. and the TOLSURF (Trail Of Late SURFactant) study group recently published initial data showing no difference in BPD between infants treated with late surfactant or placebo; however, long-term pulmonary data are still being collected.[144]

Several nutritional and fluid balance strategies have been considered to decrease BPD. Although fluid restriction in the first week after birth does not reduce BPD,[145] it is important to avoid fluid overload, administration of colloid and sodium supplementation. A retrospective evaluation of 400- to 1000-g infants demonstrated that a higher fluid intake and less weight loss in the first week of life was associated with a higher incidence of BPD.[146] Aggressive treatment of symptomatic PDA may reduce the severity of BPD, but this remains controversial.

Appropriate nutrition, both in utero as well as postnatally, is critical in helping to promote normal lung growth, maturation, and repair. Infants born with in utero growth restriction (IUGR) have an increased risk of developing BPD.[147,148] Rapid weight gain and crossing of centiles, however, may be undesirable, particularly in infants that are small for gestational age.[149] Long-chain polyunsaturated fatty acids (LCPUFAs) are important for cell membrane function as well as for their antiinflammatory role, and animal data support that docosahexaenoic acid (DHA) in particular is critical for alveolarization. Cohort studies suggest that low levels of DHA are associated with increased BPD, and maternal DHA supplementation while breastfeeding is associated with decreased BPD.[150,151] Additionally, a small clinical trial comparing soy-based versus fish oil–based lipid suggests that soy-based lipids are associated with an increased risk of BPD.[152] Meta-analysis of seven randomized trials has demonstrated that systemic supplementation with vitamin A in sufficient quantities to establish normal serum retinol concentrations reduces oxygen dependence at 36 weeks postmenstrual age (PMA).[153] However, follow-up studies showed no improvement in long-term respiratory outcomes in vitamin A–

treated infants. Additionally, after a national vitamin A shortage, units reported no difference in BPD during the period when they were unable to provide this treatment.[154–155]

One of the only pharmacologic approaches or supplements shown to reduce the risk for BPD is caffeine. A large-scale clinical trial (the Caffeine for Apnea of Prematurity, or CAP, trial) was initially developed to examine the effects of early and prolonged use of caffeine on late neurocognitive outcomes. Analysis of other endpoints related to this study suggests that caffeine significantly reduced the risk of BPD.[156] This effect is more striking than the benefit previously observed with vitamin A treatment.[153] Although mechanisms whereby caffeine reduced BPD risk are uncertain, treated infants also had a decreased need for surgical PDA closure, and respiratory support was discontinued earlier. A subgroup analysis of the CAP trial suggested that early initiation of caffeine (before DOL 2) provided greater reduction in BPD incidence than late initiation (DOL 3–10).[157] This finding was replicated in three retrospective cohort studies.[158–160] An ongoing RCT will compare early (DOL1) caffeine administration with late (DOL 2 or beyond).

Corticosteroid therapy, primarily directed at reducing lung inflammation, remains one of the most controversial areas of BPD care. Acute treatment with steroids improves lung mechanics and gas exchange and reduces inflammatory cells and mediators in tracheal samples of patients with BPD.[161,162] Meta-analysis of randomized trials suggests that corticosteroids reduce chronic oxygen dependency at 28 days and 36 weeks PMA, both when given early (before 8 days) and late.[163,164] However, there are significant concerns regarding increased mortality and adverse effects on head growth, neurodevelopmental outcomes, and lung structure, particularly with the use of dexamethasone.[165,166] Other side effects include systemic hypertension, hyperglycemia, cardiac hypertrophy, intestinal perforation, poor somatic growth, sepsis, intestinal bleeding, and myocardial hypertrophy. Currently the routine use of early high-dose steroids in premature newborns is strongly discouraged, as reflected in editorial statements from the American Academy of Pediatrics.[166] The adverse findings, however, are generally based on data from older studies that have used high doses of dexamethasone for prolonged periods of time, and many questions persist regarding the risk-benefit relationship with the use of other steroids for shorter study periods. The DART trial (Dexamethasone: A Randomized Trial) was designed to investigate if lower dose courses of dexamethasone would be safe; however, it was unable to recruit the target number of patients. The investigators showed improved extubation rates in the short term and no significant difference in long-term adverse outcomes; however, these results should be interpreted with caution given insufficient power to determine long-term safety.[167,168] Doyle et al. published a meta-analysis of postnatal corticosteroid therapy and long-term outcomes, showing that the risk of death or neurodevelopment delay is inversely related to the risk of BPD.[169] As a result, some centers advocate the use of steroids at lower doses and shorter durations (5–7 days) in ventilator-dependent infants with severe, persistent lung disease after 1–2 weeks of age.[170] A recent study on prophylactic low-dose hydrocortisone therapy demonstrated a decreased incidence of BPD; however, it also showed a nonsignificant trend toward culture-proven sepsis.[171] Interestingly, this study demonstrated sex-specific differences, with hydrocortisone showing greater benefit in female infants than males.

To avoid the adverse effects associated with systemic administration, steroids have also been given by inhalation. Although meta-analysis has shown no significant benefits using this route, a recent trial of early inhaled budesonide demonstrated significantly decreased rates of BPD.[172,173] However, infants treated with budesonide showed a nonsignificant trend toward increased mortality and culture-proven sepsis, leaving uncertainty regarding the risk/benefit profile of inhaled steroids.

Owing to the association of *U. urealyticum* infection with the subsequent development of BPD, several studies have tried to determine whether treatment with macrolides would decrease the incidence of BPD. Although none of the individual studies demonstrated benefit, a meta-analysis showed a small decrease in the incidence of BPD in infants treated with azithromycin, with a number needed to treat (NNT) of 9.6 infants.[174] Owing to the small sample size, heterogeneity of patients and unclear blinding in some of the trials, this has not yet become widespread in clinical practice and larger RCTs are needed. A subgroup analysis of one of the trials revealed a benefit in infants who were colonized with *Ureaplasma*.[175]

In clinical studies, inhaled nitric oxide (iNO) therapy acutely lowered PVR and improved oxygenation in patients with PH in various settings, including premature infants with severe RDS and established BPD.[176–178] Experimental data have demonstrated that iNO therapy may be lung-protective in several animal models of experimental BPD and, importantly, may be associated with increased alveolar and vascular growth.[179] The potential role of iNO in the prevention of BPD has received considerable attention over the past decades, but the results of randomized trials for the prevention of BPD have yielded conflicting results. A large multicenter trial showed a 50% reduction in BPD and death in preterm infants who weighed more than 1000 g at birth.[180] Another large multicenter study suggested that prolonged iNO therapy at higher doses reduces BPD when started before the second week of life and improves some respiratory outcomes during infancy.[181] However, a third large-scale study showed no effects when administered to preterm infants with minimal respiratory disease.[182]

Overall, these findings suggest that iNO therapy may lower the risk for BPD in some preterm infants. However, because of the differences between studies (including gestational age, onset and duration of therapy, dose, and related questions), recommendations for its routine use for the prevention of BPD were not supported at a recent NICHD-sponsored Consensus Conference.[183]

# Treatment

## Oxygen

Supplemental oxygen remains a mainstay of therapy for infants with BPD, yet the most appropriate target for oxygen saturation levels remains controversial. Growing concerns regarding the adverse effects of even moderate levels of oxygen therapy have led many neonatologists to accept oxygen saturations below 85%–90% early after birth of preterm newborns. Studies have shown that levels of equal to or less than 92% compared with equal to or greater than 95% are associated with a shorter duration of supplemental oxygen requirement[184] and perhaps fewer respiratory exacerbations.[185] Results from the NeOProM (Neonatal Oxygenation Prospective Meta-analysis) large multicenter collaborative trials found that targeting oxygen saturations between 85% and 89% was associated with higher mortality in comparison with infants treated with oxygen saturations targeted between 91% and 95%.[186,187] There were no differences in rates of BPD, retinopathy of prematurity, or neurodevelopment adverse outcomes. These results must interpreted with caution, as there was significant overlap in the oxygen saturation range that infants realistically spent time in as well as a problematic algorithm in pulse oximeters, potentially skewing results.[186,187] Currently most pulmonologists recommend maintaining infants with established BPD at oxygen saturations of 92%, with slightly higher levels for BPD infants with growth failure, recurrent respiratory exacerbations, or PH. Concerns persist that targeting higher levels (>95%) may be associated with ongoing lung injury due to oxidative stress. Prolonged monitoring of oxygenation while the infant is awake, asleep, and during feeds is important to ensure the avoidance of hypoxia while adjusting oxygen therapy.

In most neonatal intensive care units (NICUs), nCPAP, high-flow nasal cannulas, and noninvasive positive pressure ventilation (NIPPV) are used to maintain adequate oxygenation and ventilation while avoiding the need for prolonged ventilation or reintubation. Recent data from the Prematurity and Respiratory Outcomes Program (PROP) show a probability of 230- to 286-week infants being on different forms of respiratory support based on postnatal age (Fig. 20.11).[18] These prospectively collected data from multiple centers reflect current practice trends in respiratory support and include infants treated with heated high flow (HHF). HHF is being increasingly used, with benefits including improved perceived comfort, less nasal trauma, and easier positioning for feeding and holding infants.[188] Drawbacks are the imprecision and uncertainty in generated pressure delivered as well as lack of robust safety data. Studies that have compared HHF to nCPAP as the either the primary mode of respiratory support or for preventing extubation failure have evaluated older gestational-aged infants, excluding those at highest risk for BPD.[188] The HIPSTER (nasal high-flow therapy for primary respiratory support in preterm infants) trial, a large ongoing multicenter noninferiority trial comparing HHF to CPAP for infants born between 28 and 36 weeks, was stopped early as interim analysis showed that HHF was inferior to CPAP for respiratory support in VLBW infants.[189] Additionally, a recent retrospective evaluation suggested that use of HHF in infants weighing 1000 g or less was associated with an increased number of ventilator days, increased need for postnatal steroids and prolonged length of hospitalization, again raising concerns that HHF may not provide adequate support for the most at-risk infants.[190]

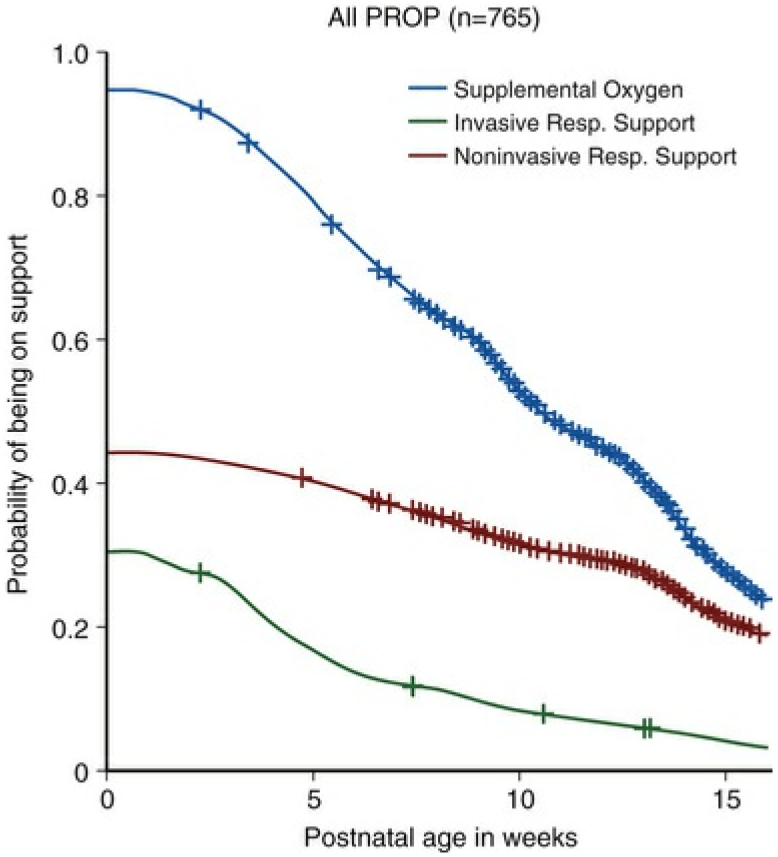

**FIG. 20.11** Respiratory support for infants of very low birth weight over the initial postnatal course. *PROP,* Prematurity and Respiratory Outcomes Program. (From Poindexter BB, Feng R, Schmidt B, et al. Comparisons and limitations of current definitions of bronchopulmonary dysplasia for the prematurity and respiratory outcomes program. *Ann Am Thorac Soc*. 2015;12:1822-1830.)

Whereas several studies have examined the role of early nCPAP in lieu of endotracheal intubation during the first week after birth, there are no studies regarding benefits of the prolonged use of nCPAP in established BPD with chronic respiratory failure. There have been conflicting results concerning whether NIPPV is equal to or superior to nCPAP for supporting infants with evolving BPD. The largest RCT showed no difference in death or incidence of BPD when comparing infants extubated to NIPPV versus nCPAP[191]; however, a meta-analysis suggests that NIPPV may be superior in preventing extubation failure.[192] This will be an ongoing area for investigation. One additional ventilatory strategy, neurally adjusted ventilatory assist, or NAVA, is being used to improve synchronization with the infant. Noninvasive NAVA has been used in infants as young as 24 weeks, but minimal literature currently exists in terms of feasibility and safety for this technology in infants at risk for BPD.[193]

In some infants with BPD, signs of severe respiratory distress persist despite nCPAP or high-flow nasal cannula therapy, including marked dyspnea, head bobbing, retractions, tachypnea, intermittent cyanosis, and $CO_2$ retention. If subsequent attempts at weaning are not successful, these infants may benefit from reintubation and the consideration of tracheostomy for chronic ventilator support. The timing and patient selection for tracheostomy and the commitment to more prolonged ventilator support are highly variable between centers. Tracheostomy and chronic ventilator support may provide a stable airway to allow for more effective ventilation and less respiratory distress, with enhanced cardiopulmonary function as reflected by lower oxygen requirements and less PH. Greater respiratory stability often improves tolerance of respiratory treatments, physical therapies and handling by staff and family members, thereby improving maternal-infant interaction and neurodevelopmental outcome. Detailed care of ventilator-dependent BPD infants is beyond the scope of this chapter, but successful management requires well-organized, multidisciplinary teams to address the complexity of issues.

## Drug Therapies

Multiple pharmacologic therapies have been used in the management of BPD, including diuretics, bronchodilators, and steroids. Despite observations that suggest acute improvement with many of these interventions, data are limited regarding the long-term safety and efficacy of many drugs used in infants with BPD.

## Diuretics

Diuretics improve pulmonary compliance and airway resistance by reducing lung edema. Two Cochrane Systematic Reviews assessed the effects of loop diuretics (furosemide) and those acting on the distal renal tubule (thiazides and spironolactone) for preventing or treating BPD in preterm infants.[194,195] Chronic furosemide therapy can improve oxygenation and lung compliance in infants with BPD.[196] A small study suggested that furosemide (1 mg/kg q12h intravenously or 2 mg/kg q12h orally) can improve weaning from the ventilator when compared with placebo.[197] Thiazides and spironolactone can improve lung function, but this finding has not been consistent.[198,199] Although diuretics generally cause short-term improvements in lung compliance, there is little evidence of sustained reduction in ventilator support, length of hospital stay, or other long-term benefits.

## Bronchodilators

Infants with BPD have airway smooth muscle hypertrophy and often have signs of bronchial hyperreactivity that acutely improve with bronchodilator therapy, but response rates are variable.[200,201] Data showing long-term benefit of bronchodilators (including beta agonists and anticholinergic agents) for the prevention or treatment of BPD are lacking. In addition to their roles in apnea, aminophylline and caffeine can reduce airway resistance in infants with BPD and may have an additive effect with diuretics. Methylxanthines can improve weaning of infants from MV,[202] but side effects such as jitteriness, seizures, and gastroesophageal reflux are recognized. As described earlier, caffeine use has been shown to reduce BPD, PDA, and cerebral palsy.

## Steroids

Steroids are generally used to reduce lung inflammation in BPD. The use of corticosteroids to prevent BPD has already been discussed. Late systemic glucocorticoids can be used to improve lung mechanics and gas exchange, facilitating earlier extubation. Although commonly used in infants with asthma, inhaled steroids have not consistently showed improvement in lung function in BPD. As discussed earlier regarding BPD prevention, the side effects of poor head growth and neurocognitive outcomes with early and prolonged high-dose strategies are unacceptable risks for preterm infants at risk for BPD. However, steroid bursts (high doses for 3–5 days) may be helpful in the management of BPD infants with acute deterioration of lung function.

## Antiviral Immunization

Infants with BPD are at increased risk of recurrent respiratory tract infections, especially those due to respiratory syncytial virus (RSV). Treatment with RSV immunoglobulin or RSV monoclonal antibodies is effective in preventing hospital readmissions. A large multicenter study of palivizumab, a humanized monoclonal antibody against RSV, found that monthly injections of 15 mg/kg for 5 months reduced hospitalization rates for RSV infection by 5% in infants with BPD.[203,204] The American Academy of Pediatrics recommendations include the use of palivizumab or RSV intravenous immunoglobulin prophylaxis for infants and children with BPD during the first year of life during RSV season. Older infants with more severe BPD, with continued oxygen requirement, diuretic requirement, or steroid requirement during the 6 months prior to RSV season, may benefit from prophylaxis for two RSV seasons.[204]

## Pulmonary Hypertension

The initial clinical strategy for the management of PH in infants with BPD begins with treating the underlying lung disease. This includes extensive evaluation for chronic reflux and aspiration, structural airway abnormalities (e.g., tonsillar and adenoidal hypertrophy, vocal cord paralysis, subglottic stenosis, and tracheomalacia), assessments of bronchial reactivity, improving lung edema and airway function, and other pulmonary considerations. Periods of acute hypoxia, whether intermittent or prolonged, can often contribute to late PH in BPD. A sleep study may be necessary to determine the presence of noteworthy episodes of hypoxia and whether hypoxemia has predominantly obstructive, central, or mixed causes.

Additional studies that may be required include flexible bronchoscopy for the diagnosis of anatomic and dynamic airway lesions (e.g., tracheomalacia) that may contribute to hypoxemia and poor clinical responses to oxygen therapy. An upper gastrointestinal series, pH or impedance probe, and swallow study may be indicated to evaluate for gastroesophageal reflux and aspiration that can contribute to ongoing lung injury. If the findings are positive or even if clinical suspicion remains high in the face of negative findings and in the setting of lung disease that fails to improve, consideration should be given to gastrostomy tube placement and fundoplication. For patients with BPD and severe PH who fail to maintain near-normal ventilation or require high levels of $FiO_2$ despite conservative treatment, consideration should be given to chronic MV support.

Despite the growing use of pulmonary vasodilator therapy for the treatment of PH in BPD, data demonstrating efficacy are extremely limited; the use of these agents should only follow thorough diagnostic evaluations and aggressive management of the underlying lung disease. We strongly encourage cardiac catheterization prior to the initiation of chronic therapy. Current therapies used for PH therapy in infants with BPD generally include inhaled NO, sildenafil, endothelin-receptor antagonists (ETRAs), and calcium channel blockers. Calcium channel blockers (e.g., nifedipine) benefit some patients with PH, and short-term benefits of these blockers in infants with BPD have been reported.[205] In comparison with an acute study of iNO reactivity in infants with BPD, the acute response to calcium channel blockers was poor, and some infants developed systemic hypotension. We generally use sildenafil or bosentan (an ETRA) for chronic therapy of PH in infants with BPD. Sildenafil, a highly selective type 5 phosphodiesterase (PDE-5) inhibitor, augments cyclic GMP content in vascular smooth muscle. It has been shown to benefit adults with PH as monotherapy and in combination with standard treatment regimens.[206] In a study of 25 infants with chronic lung disease and PH (18 with BPD), prolonged sildenafil therapy as part of an aggressive program to treat PH was associated with improvement in PH by echocardiogram in most (88%) patients without significant rates of adverse events.[207] Although the time to improvement was variable, many patients were able to wean off mechanical ventilator support and other PH therapies, especially iNO, during the course of sildenafil treatment without worsening of PH.

The recommended starting dose for sildenafil is 0.5 mg/kg per dose every 8 hours. If there is no evidence of systemic hypotension, this dose can gradually be increased over 2 weeks to achieve the desired pulmonary hemodynamic effect or a maximum of 2 mg/kg per dose every 6–8 hours. Data are largely lacking on other agents (e.g., ETRAs and prostacyclin analogues) in BPD infants who fail to respond to other approaches.

## Prognosis

Most follow-up data have been obtained from patients from the presurfactant era. Approximately 50% of infants with BPD will require hospital readmission during early childhood for respiratory distress, particularly if they develop respiratory syncytial virus (RSV) infection.[208] Importantly, late readmissions are not exclusively a problem of preterm infants with BPD; increased rehospitalizations, including the need for intensive care, are also observed in late preterm infants without BPD.[209] This high rate of hospitalization generally declines during the second and third years of life,[210] but lung function studies often show limited reserve even in patients with minimal overt respiratory signs.[211] This observation likely explains the severity of presentation in some infants with BPD after acquiring RSV or other infections.

Infants with severe BPD often develop chronic obstructive pulmonary disease (COPD), but impaired flows may reflect disproportionate or abnormal growth patterns between airways and the distal lung. In the majority of BPD infants, lung growth and remodeling during infancy results in progressive improvement of gas exchange, lung function, and level of oxygen therapy; few BPD patients remain oxygen-dependent beyond 2 years of age. Lung function is usually in the low-normal range by 2–3 years of age, but air flow abnormalities may remain. Infants with BPD have reduced absolute and size-corrected flow rates in comparison with age- and size-matched control patients, suggesting poor airway growth with age. Filipone and colleagues have reported a strong correlation between $V_{max}$ FRC at 2 years of age with $FEV_1$ at school age, suggesting persistent air flow limitation in selected patients with BPD.[211]

Although pulmonary function in most survivors with BPD improves over time and permits normal activity, abnormalities detected by pulmonary function testing often persist through adolescence, including increased airway resistance and reactivity.[212] Unfortunately, comprehensive longitudinal studies of the pulmonary course and lung function of adult patients with a previous history of premature birth are lacking. More studies are needed to determine the long-term respiratory course of premature neonates, with or without severe BPD, and their relative contribution to the growing adult population with COPD.

## Summary

Nearly 40 years after its original description, BPD has changed. However, it remains a significant complication of premature birth and is a persistent challenge for the future. BPD has evolved from the classical stages described initially to a disease characterized largely by inhibition of lung development. Future strategies that improve long-term outcomes will depend on successful integration of basic research on the fundamental mechanisms of lung development and response to injury, will incorporate precision medicine to apply targeted therapies given the heterogeneity of etiologies contributing to BPD, and will test novel interventions to lower the occurrence and severity of the cardiopulmonary sequelae of BPD.

# Children Dependent on Respiratory Technology

Howard B. Panitch MD

## Introduction

Children who require technology for chronic respiratory insufficiency or failure constitute a small but varied group. The US Congress's Office of Technology Assessment (OTA) defines a technology-dependent child as “one who needs both a medical device to compensate for the loss of a vital body function and substantial and ongoing nursing care to avert death or further disability.”[1] This definition does not take into account either site of care (hospital, home, or skilled facility) or credentials of the caregiver (professional nurse or trained layperson). Further, the OTA identifies four separate groups of children that would be considered technology-dependent. Two of these include children dependent on mechanical ventilation for at least part of the day and children dependent on other device-based respiratory support such as tracheostomy tubes, airway suctioning, and the use of supplemental oxygen. This chapter discusses only those children requiring technology for the treatment of chronic respiratory failure, a condition for which mechanical ventilatory support is required for at least 4 hours/day for a month or longer.[2,3]

## Epidemiology

The large-scale need for chronic respiratory support of children began with the polio epidemics of the 1930s, 1940s, and 1950s. The development of subspecialties in neonatology and pediatric critical care in the 1960s resulted in advances in medical therapies that allowed children with previously fatal conditions to survive, albeit occasionally with chronic conditions such as respiratory failure.[4] A focus on pediatric chronic respiratory failure did not occur in the United States until the early 1980s. In 1981, President Ronald Reagan waived the eligibility rules for Supplemental Security Income to allow Katie Beckett, a ventilator-dependent child, to be cared for at home without losing Medicaid benefits, thus bringing the population of children with chronic respiratory failure into the national spotlight.[5] In 1982, the surgeon general then convened the Workshop on Children with Handicaps and Their Families, where he noted that advances in medical interventions created a new type of disability: infants chronically dependent on ventilatory support as a result of other medical interventions, which he referred to as "a creature of our new technology."[6]

The causes of chronic dependency on mechanical ventilation or supplemental oxygen can be categorized as (1) those that affect the respiratory pump (respiratory muscles, rib cage, ventral abdominal wall); (2) those that affect respiratory drive; (3) extrathoracic and central airway lesions; and (4) pulmonary parenchymal and vascular abnormalities (Table 21.1). Individual patients can have more than one cause for chronic ventilator dependency (i.e., neuromuscular weakness and severe kyphoscoliosis, or anoxic encephalopathy with abnormal respiratory drive, recurrent aspiration, and obstructive sleep apnea).

**Table 21.1**

**Conditions Leading to Technology Dependence**

| Pulmonary parenchymal and vascular problems | ■ Chronic lung disease of infancy (bronchopulmonary dysplasia)<br>■ Lung hypoplasia<br>■ Recurrent aspiration syndromes<br>■ Cystic fibrosis<br>■ Congenital heart disease |

In the United States, there is no national registry that tracks the population of ventilator-assisted individuals. Center-specific surveys of children cared for in acute pediatric hospitals in the 1980s demonstrated that bronchopulmonary dysplasia (BPD) and noncardiac congenital anomalies were the most common diagnoses of infants and toddlers who required prolonged mechanical ventilation,[7–9] whereas spinal cord injury and underlying neuromuscular diseases were more common among those cared for in rehabilitation facilities.[10] In Massachusetts, surveys of children receiving chronic mechanical ventilatory support outside of acute care hospitals showed that the chief cause of chronic respiratory failure (CRF) was sequelae of prematurity or congenital malformations in the 1980s[11] and early 1990s.[12] However, over the next 15 years the major causes of CRF became neuromuscular disease and central nervous system injury or malformations.[13] In addition, the number of children receiving such care outside a hospital had nearly tripled from 1990 to 2005.[13] National surveys from Canada, Europe, and Japan have similarly demonstrated that neuromuscular disease and central nervous system injuries are the most common indications for chronic ventilation in children.[14–22] This probably reflects a philosophical change toward providing chronic respiratory support to patients with progressive neuromuscular disorders,[23,24] an increasing role of noninvasive ventilation for these patients,[25] and a reflection of the types of patients most commonly requiring prolonged care in pediatric intensive care units.[26]

The prevalence of children requiring chronic mechanical ventilation has grown over the last three decades. In 1987, the OTA estimated that there were between 600 and 2000 ventilator-dependent children in the United States.[1] Ten years later, extrapolations of a survey from Minnesota estimated that there were 17,824 ventilator-assisted individuals in the United States, of whom 5534 would be below 21 years of age.[25] It was also shown that subjects below 20 years of age represented about one-third of all ventilator-assisted individuals in the state, with those below age 11 years being the largest group and those between 11 and 20 years accounting for the greatest increase since the prior survey of 1992. This survey included only patients in whom a backup ventilator rate was used; thus the number was likely an underestimate. In the 1990s, the prevalence of children requiring chronic mechanical ventilation was estimated to be 0.5 per 100,000 in the United Kingdom,[16] 0.68 per 100,000 in Japan[18] and 1.2–1.5 per 100,000 in the United States.[9,27] Extrapolating data from Massachusetts[13] and Pennsylvania,[28] King estimated the prevalence of ventilator-assisted children cared for at home in the United States in 2010 to be 4.7–6.4 per 100,000.[29] Recent international prevalence rates of home mechanical ventilation in children below 18 years of age are similar, ranging from 4.2 to 6.7 per 100,000.[30,31] The method of mechanical ventilation has changed over time as well, with most recent surveys demonstrating a marked rise in the percentage of children supported by noninvasive ventilation and far fewer receiving ventilation via tracheostomy.[17,32–34] The overall increase in prevalence of ventilator-dependent children cared for at home is likely multifactorial, reflecting advances in the medical care of critically ill children, improved technology in home equipment and pediatric noninvasive interfaces, increased use of polysomnography in children to detect nocturnal hypoventilation and philosophical changes in the willingness of physicians to apply these technologies to children with progressive diseases.

## Goals of Therapy

The objectives of technology dependence support are largely independent of the cause of respiratory failure. They include reversing or ameliorating the cause of respiratory compromise, extending life, improving physiologic function, and reducing morbidity.[35] In infants and young children, respiratory failure can also be associated with slow growth and developmental delay; therefore chronic ventilatory support is sometimes used to avoid these consequences. Occasionally, ventilatory support is augmented during periods of physical activity to promote the child's potential for rehabilitation, or it may be increased if the child fails to maintain adequate growth velocity. Thus in formulating the daily prescription for mechanical ventilation, the desire to reduce support must be balanced with a more global view of the child's needs.

Psychosocial development and quality of life can be enhanced when chronic ventilatory support is safely accomplished outside the intensive care unit.[36] The home setting has long been considered the best place for technology dependent children in terms of their psychological and somatic development,[7,37,38] but excellent medical, psychosocial, and developmental support, including weaning from mechanical ventilation when appropriate, can be safely accomplished in inpatient rehabilitation facilities (within or outside the acute care hospital).[39–42] The setting for postacute care will depend on the degree of medical stability of the patient, the willingness and ability of family caregivers to provide care in the home, and community resources. Although the number of ventilator-dependent children has increased over the years and home care of this population has become more common, it should never be assumed de facto that home care is the best setting for an individual child or family. This can be concluded only once a full assessment of the child, family, resources, home care setting, and available alternative settings has been made. Additionally, the best location might change throughout a child's course—for instance, as the child's medical condition improves or worsens, or if caregiver availability changes.

## Pathophysiology of Respiratory Failure

Respiratory failure can result from an imbalance between the output of the respiratory pump and the load against which it has to work, development of respiratory muscle fatigue, inadequate respiratory drive, pulmonary parenchymal disease or pulmonary vascular disease.[43] The disparity between the abilities of the respiratory pump and its load refer to either inadequate pump output for the imposed load, as in the case of a child with respiratory muscle weakness, or an increased load for the output. This could be the result of a reduction in lung compliance, an increase in pulmonary resistance, or stiffening of the chest wall itself. In theory, "pump failure" results in hypercapnia, whereas parenchymal disease causes hypoxemia. In practice, however, the two often coexist, and hypoventilation from pump failure will result in hypoxemia. An understanding of the causes of respiratory failure often provides a rationale for the type of assisted ventilation that will provide the best support for the individual. It is critical to recognize that although chronic mechanical ventilation will not alter the ultimate prognosis for chronic progressive disorders like Duchenne muscular dystrophy, spinal muscular atrophy (SMA), or cystic fibrosis, its use can still prolong survival, relieve dyspnea, and improve daytime function and quality of life for children with such disorders.

## Inadequate Pump Output (e.g., Neuromuscular Disease, Spinal Cord Injury)

There is a typical progression of respiratory morbidity in patients with neuromuscular disease (NMD).[44] Once weakness of respiratory muscles is present, airway clearance becomes compromised, predisposing patients to recurrent episodes of lower respiratory tract infections and atelectasis. This results in a decrease in lung compliance and therefore an increase in the load against which the respiratory pump must work. Infants and young children with NMD are more likely to experience complications from mucus plugging because their airways are smaller and peripheral airways contribute a greater proportion of intrathoracic resistance in children under 5 years.[45] Early in childhood, the chest wall of children with NMD is abnormally compliant[46]; as a result, the effect of chest wall recoil on lung volume and airway caliber is reduced, and this contributes to intrathoracic airway narrowing.

There are also ventilatory consequences of this alteration of chest wall compliance. In the young child with neuromuscular weakness and a highly compliant chest wall, much of the work of the respiratory muscles can be wasted as chest wall retractions reduce the contribution of the thoracic compartment to ventilation. Contraction of intercostal muscles can help to maintain tidal volume, but at the cost of increased respiratory energy expenditure; thus adequate ventilation can be maintained, but growth failure might ensue. In very young children, the imbalance between the highly compliant chest wall and relatively stiff lungs can result in an acquired pectus excavatum deformity.[47–49] Acquired chest wall deformity like this has led to the theoretical concern that when chronic low-volume breathing is present in infants, it can also impair lung growth and development,[50] although this has never been demonstrated. Nevertheless, noninvasive ventilation has been used to correct or prevent the development of pectus excavatum in young children with NMD.[47–49]

Over time, the chest wall of subjects with neuromuscular weakness becomes stiffer than normal because of prolonged periods of low-tidal-volume breathing without deep sigh breaths. This leads to the development of ankylosis around costovertebral joints, with stiffening of ligaments and tendons. When present, the progression of kyphoscoliosis will contribute to a mechanical disadvantage around the costovertebral joint, making the respiratory muscles less efficient. The sum of these imbalances results in a restrictive pattern of lung function, with reduced vital capacity and total lung capacity. If subjects have significant expiratory muscle weakness, however, the residual volume and functional residual capacity can be normal or even slightly elevated, because the rib cage cannot be reduced below its normal resting volume.

As weakness progresses, patients experience episodes of hypoventilation during sleep, especially during rapid-eye-movement (REM) sleep. Obstructive apnea can also occur because of weakness of the bulbar musculature or physical features of certain neuromuscular diseases such as macroglossia, retrognathia or flattening of the malar eminences.[51] When respiratory muscle weakness becomes sufficiently severe to cause hypoventilation during sleep, the patient will compensate with an arousal response. This protective mechanism causes sleep disruption and fragmentation, poor sleep quality, and reduced sleep time.[44] These phenomena, in turn, can cause daytime somnolence and fatigue as well as poor school performance.[52] Initially, patients will demonstrate hypercapnia during sleep, but they will be able to maintain normocapnia while awake. As the severity of sleep-disordered breathing increases, either because of prolonged periods of nocturnal hypoventilation, mechanical alterations of the respiratory system or both, central drive becomes blunted and the patient does not respond in an appropriate way to the challenge of elevated $PaCO_2$. At this point, diurnal hypercapnia will occur, but the daytime hypercapnia can be corrected if nocturnal mechanical support of breathing is instituted.[53] Further progression of weakness, however, will result in ineffective ventilation during the day and diurnal hypercapnia, even when nocturnal ventilation has been instituted.[54]

Timing of the progression of respiratory failure varies with different NMDs. In the absence of ventilatory support, infants with SMA who are unable to sit typically die by 2 years of age.[55] Boys with Duchenne muscular dystrophy, in contrast, do not exhibit respiratory compromise until their second decade of life. Respiratory muscle weakness in congenital myopathies is often static, but as children grow, their status may deteriorate because the respiratory muscles cannot compensate for the increase in body mass. Respiratory failure often ensues during the pubertal growth spurt. Some disorders, like myotonic dystrophy or myelomeningocele with Chiari malformation, are associated with primary disorders of ventilatory control.[56,57]

Paralysis of the diaphragm results from cervical injury above C-3 or from phrenic nerve injury, often in the setting of birth trauma, cardiac surgery or other thoracic surgery. Infants can occasionally compensate for unilateral paralysis, but bilateral diaphragmatic paralysis requires ventilatory support. When unilateral diaphragmatic paralysis causes respiratory failure, plication of the affected diaphragm often improves ventilation sufficiently that mechanical support is not required. If the paralysis is the result of trauma, plication does not prohibit recovery of function of the diaphragm.

## Abnormal Respiratory Pump (e.g., Early-Onset Scoliosis, Asphyxiating Thoracic Dystrophy, Severe Kyphosis)

The respiratory pump itself can present a load too great to be overcome by the muscles of respiration. Distortion of the thoracic cage from early-onset scoliosis results in a restrictive pattern of lung function.[58,59] A reduction in chest wall compliance can occur when ribs are congenitally fused, the intercostal muscles are replaced by fibroconnective tissue after years of disuse or when costovertebral joints become ankylosed from chronic low-tidal-volume breathing without sigh breaths. Alternatively, distortion of the thoracic cage can place the inspiratory muscles at sufficient mechanical disadvantage that their force-generating ability is compromised. Then the thoracic compartment is noncompliant, and the majority of the volume change that occurs with ventilation is in the abdominal compartment. *Thoracic insufficiency syndrome* is a term used to describe conditions where the thorax cannot support normal ventilation or lung growth.[60] Since the volume of the thorax is small in these patients, tidal volume targets during mechanical ventilation are smaller as well.

## Abnormal Respiratory DrivE (e.g., Congenital Central Hypoventilation Syndrome, Chiari Malformation, Brain Stem Lesions, Leigh Disease)

Several rare disorders result in an abnormal response to hypercapnia and hypoxemia. Congenital central hypoventilation syndrome (CCHS) represents a failure of autonomic control of breathing; it is caused by a defect in the paired homeobox 2B *(PHOX2B)* gene, which produces a transcription factor essential to migration of neural crest cells and development of the autonomic nervous system.[61–63] There is a range of ventilatory abnormalities in children with CCHS, so that some children present in the neonatal period with chronic alveolar hypoventilation, requiring around-the-clock ventilatory support, while others may not present until adulthood.[63] Often, as infants grow older, they are able to breathe adequately without support while awake but require ventilatory assistance during sleep and with acute illnesses. Because patients with CCHS do not respond appropriately to hypoxemia or hypercarbia, their mechanical ventilation strategy requires a mandatory rate to assure adequate ventilation. Since the underlying lung parenchyma and chest wall are normal, the delivered tidal volume should be normal as well.

Prader Willi syndrome and rapid onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation (ROHHAD) represent two other disorders associated with potentially severe hypoventilation.[61,62] The majority of children with Prader-Willi syndrome have a deletion of the long arm of chromosome 15, whereas the genetic abnormality leading to ROHHAD is currently unknown. Both conditions are associated with hyperphagia and the rapid onset of obesity, but children with ROHHAD also have problems with salt and water balance. The presence of obesity in both conditions can also cause obstructive sleep apnea and contribute to sleep-related hypoventilation. Obesity hypoventilation syndrome—defined as a body mass index (BMI) greater than 30 kg/m$^2$, daytime hypercapnia and hypoxemia, and sleep-disordered breathing—is another cause of respiratory failure in children,[64] although its pathophysiology is not well understood.

Children with Chiari malformation demonstrate a blunted response to hypercapnia, suggesting a central chemoreceptor problem.[62] They may also have both central and obstructive apnea during sleep. Thus assuring adequate minute ventilation and providing necessary distending pressure to overcome upper airway obstruction are both important strategies in supporting these patients. If the Chiari malformation is accompanied by myelomeningocele and kyphoscoliosis, adjustment of the tidal volume will be necessary.

## Parenchymal Lung or Intrathoracic Airway Disease (Bronchopulmonary Dysplasia, Cystic Fibrosis, Tracheomalacia,

## Bronchiectasis)

The majority of children in this category of respiratory failure are those with chronic sequelae of neonatal lung disease. Approximately 1.5% of all newborns develop bronchopulmonary dysplasia (BPD) (chronic lung disease of infancy),[65] making it the most common cause of chronic obstructive lung disease among infants. A recent point prevalence study showed that 36.5% of infants hospitalized in eight tertiary referral neonatal intensive care units fulfilled criteria for severe BPD, defined as those born after less than 32 weeks' gestation and receiving ≥30% or more supplemental oxygen and/or positive pressure ventilation at 36 weeks postmenstrual age (PMA).[66] Among the infants with severe BPD, 41% were still supported by positive pressure ventilation at 36 weeks PMA, suggesting that they are at greater risk to require prolonged mechanical ventilation.[67] BPD is associated with lung hypoplasia resulting from the arrest of alveolar development, but there is also evidence of parenchymal scarring, air trapping and distortion of lung architecture. The central airways can become deformed from cyclic positive pressure distension, leading to acquired tracheomalacia or bronchomalacia. These abnormalities lead to a decrease in lung compliance and conductance, increasing the respiratory pump load. Severe air trapping can impair diaphragm contractility by altering its length-tension relationships. These can all result in an unfavorable balance between respiratory pump output and load, leading to chronic respiratory failure and a need for prolonged mechanical ventilation. The energetics of breathing may comprise as much as 25% of the infant's caloric needs. Thus, if weaning from mechanical ventilation is too aggressive, some infants with BPD can maintain adequate gas exchange, but only at the expense of growth and development. The need for supplemental oxygen will depend on the extent of parenchymal damage, hypoplasia, or ventilation/perfusion mismatch. Most infants with BPD who require chronic mechanical ventilation develop respiratory failure while in the neonatal intensive care unit and do not recover before the time when they are otherwise considered ready for discharge. Occasionally, however, chronic respiratory failure ensues after discharge in the setting of an acute viral lower respiratory illness. Prolonged mechanical ventilation is appropriate in both settings, as lung function is expected to improve with growth and postnatal lung development.

In recent years chronic mechanical ventilation of patients with cystic fibrosis (CF) has been performed, first as a bridge to lung transplant and subsequently as a palliative measure. Like other patients whose respiratory pump becomes inadequate for the load, patients with CF and severe airway obstruction develop a rapid, shallow breathing pattern that is inefficient.[68,69] When challenged with an increased load or imposed hypercapnia, the mechanics of the respiratory system limit the patient's response.[68–70] As obstruction worsens, dynamic compliance of the lung falls as well, contributing to an increased respiratory load.[69] At the same time, downward displacement of the diaphragm from hyperinflation places it in a less favorable mechanical position, contributing to inefficiency of the respiratory pump.

## General Considerations for Home Care

Often, the need for chronic mechanical ventilatory support is determined following an acute illness, when the child is unable to wean from mechanical ventilation. In other children, the requirement for chronic mechanical ventilation is recognized following an abnormal polysomnogram or identification of other nonacute indicators such as poor growth or chronic dyspnea. No matter the presentation, once it has been decided that chronic mechanical ventilation is necessary for the support of a child, the eventual site of long-term care must be determined. This requires assessment not only of the medical stability and suitability of the child but also of the family as potential medical caregivers. Other decisions regarding the approach to the child's care (e.g., the performance of a tracheostomy) require careful consideration as to how the choice of the child's site of care will be affected.

A child's medical stability must be evaluated within the context of the site of care. The required level of stability at the time of transfer from a pediatric intensive care unit (PICU) will differ between home and a care site within a hospital or a subacute care facility (Table 21.2).[35,39] In any setting, the child must have a stable airway (natural or tracheostomy), have blood gas values that are appropriate for the underlying diagnosis, and not have care demands that exceed the resources of the site of care. When a child goes home supported by mechanical ventilation for the first time, there should be no changes in the medical plan for at least 1 week before discharge to assure that the child is adequately supported on the proposed regimen. In addition, any change to the medical regimen within 1 week of the initial hospital discharge has been associated with unanticipated readmission within 1 month of the child's going home.[71]

## Table 21.2

### Criteria for Medical Stability

| **Home** | **General Hospital Ward/Transitional Care Facility** |
|---|---|
| **CLINICAL** | |
| Positive trend on growth curve | No need for 1 : 1 nursing care |
| Stamina for periods of play | No invasive monitoring |
| No frequent fevers or infections | No need for intravenous vasopressors or vasodilators |
| **PHYSIOLOGIC** | |
| Stable airway | Mature tracheostomy ≥ 1 week postoperatively |
| $PaO_2$ ≥60 torr in $FiO_2$ ≤0.4 | $SpO_2$ >92% in $FiO_2$ ≤0.40 |
| $PaCO_2$ <50 torr (parenchymal disease) or <45 torr (chest wall or neuromuscular disease) | Stable blood gases within normal range for the diagnosis |
| No need for frequent ventilator setting changes | Stable ventilator settings ≥1 week |

Modified from Make BJ, Hill NS, Goldberg AI, et al. Mechanical ventilation beyond the intensive care unit. Report of a consensus conference of the American College of Chest Physicians. *Chest* 1998;113:289S-344S and Ambrosio IU, Woo MS, Jansen MT, Keens TG. Safety of hospitalized ventilator-dependent children outside of the intensive care unit. *Pediatrics* 1998;101:257-259.

When a technology-dependent child is being discharged to home, two adults must be willing and able to learn and assume all aspects of the child's daily care, including dosages and indications for all medications being used, feedings, respiratory assessment, ventilator assessment and troubleshooting, and equipment care.[72] For children with weak or ineffective cough, caregivers must learn various techniques of airway clearance to avoid atelectasis or treat acute illnesses. If the child will receive mechanical ventilation through a tracheostomy, the family caregivers must also learn how to suction the artificial airway and perform routine and emergency tracheostomy tube changes. In addition, there must be adequate financial support from third-party payers to provide the equipment and supplies necessary to care for the child at home. The residence in which the child will be cared for must have adequate space for the child, equipment, and visiting health care providers. The home must have running water, heat, electricity and a working telephone. Entrances must be accessible for a patient confined to a wheelchair.

The amount of skilled nursing care the family will require must also be included in the discharge plan. All families of children who cannot correct an airway or ventilator problem, or call for help, should be offered skilled nursing care for at least a portion of the day to allow caregivers to sleep with the reassurance that the child's welfare is not at risk. Funding for those services, which are the most expensive component of the home care of technology-dependent children,[2] should be guaranteed by third-party payers with periodic reassessments established to determine ongoing needs. In some health care systems outside of the United States, personal care attendants rather than nurses are funded to perform some of these services and to facilitate the patient's full participation in society at a lower cost.[73,74] Although there are no uniform criteria for establishing the number of nursing hours provided, this should be determined by the medical needs of the child, the capabilities of the family, and other demands on family providers (work, other children in the home, etc.). Funded respite care, to allow caregivers time off from continuous medical care and monitoring of the child, should also be built into the discharge plan, as this has repeatedly been identified as an essential component to help relieve stress and caregiver burnout.[75–80]

## Treatment of Chronic Respiratory Failure

### Noninvasive Ventilation

Noninvasive ventilation (NIV) refers to correction of alveolar hypoventilation or upper airway obstruction without the use of artificial airways (endotracheal or tracheostomy tubes). It is usually used at night, rather than continuously, but if a child has a progressive disorder or experiences an acute decompensation, NIV can be used 24 hours/day.[81] For patients with NMD or chest wall restriction who develop symptomatic hypercapnic respiratory failure, 4 hours or more of nocturnal NIV per day can cause a sustained decrease in daytime $PaCO_2$ and resolution of symptoms related to sleep-disordered breathing.[82] For instance, nocturnal NIV corrected diurnal hypercapnia and severe nocturnal hypoventilation and maintained normal daytime $PaCO_2$ for an extended period in a group of 23 young men with Duchenne muscular dystrophy.[83] In this series, nocturnal NIV was associated not only with improved survival (85% at 1 year, and 73% from 2 through 5 years) but also with sustained improvement in daytime gas exchange throughout the 5-year duration of the study.

The proposed mechanisms by which nocturnal NIV improves overall function in patients with restrictive disorders include resting of the respiratory muscles to reverse fatigue,[84] improving lung and chest wall mechanics by reversing areas of microatelectasis, increasing chest wall excursion[82,85–88] and resetting central chemoreceptor sensitivity to $CO_2$.[82,85] These mechanisms are not necessarily mutually exclusive, but evidence that NIV improves lung or chest wall mechanics in a sustained way is lacking. Several series involving subjects with a variety of neuromuscular diseases failed to demonstrate an increase in vital capacity after the institution of NIV,[82,85–87] and the institution of NIV in young men with Duchenne muscular dystrophy before the onset of respiratory failure failed to slow the expected decline in vital capacity.[88] It may be that episodic chest inflations closer to total lung capacity, or “lung volume recruitment maneuvers,” are required to alter the decline in vital capacity.[89,90] Furthermore, direct measurements of lung and chest wall compliance after 3 months of NIV did not change in a series of 20 patients with neuromuscular disease and restrictive defects.[82] By contrast, the investigators demonstrated enhanced responsiveness to $CO_2$ in these subjects after 3 months of NIV, suggesting a resetting of central chemoreceptors and enhancement of respiratory drive. Another study showed that nocturnal NIV can restore $CO_2$ responsiveness by an alternate method: reduction of respiratory muscle fatigue and improvement in respiratory muscle endurance.[54] Investigators calculated the tension time index of the respiratory muscles, a noninvasive measurement of the likelihood of muscle fatigue, in 50 subjects with Duchenne muscular dystrophy just after they ended a night of NIV support (8 a.m.) and again just before they resumed nocturnal NIV (8 p.m.). To assess respiratory muscle endurance, the authors also measured the time to fatigue ($T_{\text{lim}}$) after pressure threshold loading under the same conditions. There was a progressive increase in the tension time index and a decrease in $T_{\text{lim}}$ that correlated with the progression of symptoms. In the most affected subjects, however, the tension time index decreased and $T_{\text{lim}}$ increased significantly following a night of NIV support. Thus these data suggest that nocturnal NIV can unload weakened respiratory muscles, thereby improving their daytime capacity and reducing their fatigability.

Although noninvasive ventilation is usually confined to those who require support for 16 hours/day or less, it has been used successfully in patients who require continuous support.[81,91] This can be achieved either by a nasal interface or by mouthpiece.[81,91,92] Contraindications include poor glottic function, inability to achieve adequate ventilation noninvasively, patient preference, and lack of caregiver expertise.[81] However, sometimes NIV has been used successfully in infants with SMA and children with static encephalopathy who have impaired glottic function.[93] The use of NIV has been recommended by some over ventilation via tracheostomy for palliation of dyspnea in severely affected infants with SMA type I.[55]

Complications of positive-pressure NIV are related to either the interface itself or misdirection of the applied pressure. Choices of nasal or oronasal interfaces for infants and small children are limited, so adaptation of adult interfaces is often necessary.[94] Poorly fitting interfaces lead to leaks that not only interfere with adequacy of ventilation but also can cause eye irritation. In response, straps are often tightened to reduce the leak. This can cause facial erythema and skin ulceration.[95,96] Use of a custom-molded mask[95,97] or an alternate interface with different pressure points can reduce this complication, but attention to skin integrity is an integral component of care of the child receiving positive-pressure NIV. Skin ulceration can preclude the ability to provide effective NIV and force a decision to advance to tracheostomy. Prolonged application of pressure by nasal interfaces on the growing face has been associated with midface flattening.[95,98,99] Although special devices have been created to correct this,[99] use of more than one interface with different pressure points or a custom-molded mask[100] should be considered.

High flows related to NIV can cause nasal congestion and mouth dryness[101]; these deleterious side effects can be ameliorated by humidifying the circuit. The positive pressure applied during NIV has been associated with ear and sinus pain in adults[102] and retrograde lacrimal duct flow in children,[103] and higher positive pressures can cause aerophagia. Gastric distension, in turn, can impair the effectiveness of NIV by creating abdominal competition for lung expansion.

## Ventilation via Tracheostomy

Invasive ventilation via tracheostomy is typically used in infants and children with parenchymal lung or congenital heart disease. In addition it is used in young children who require continuous mechanical ventilation, those with severe craniofacial malformations (or other causes of upper airway or central airway obstruction that cannot be corrected by NIV) and those with severe developmental delay.[3,8,104] Whenever possible, relatively small tracheostomy tubes are used to allow for a leak[35,105]: this facilitates speech and avoids damage to the tracheal wall. When leak around the tracheostomy tube is large, however, effective mechanical ventilation can be compromised. This is especially true if the child is being ventilated in a volume-control mode, since the large leak will prevent adequate development of intrathoracic pressure to expand the chest because the ventilator breath escapes through the mouth and nose. The leak may be variable, so that even when mechanical ventilation is adequate during awake hours, significant hypoventilation can occur during sleep.[106] This is remedied either by changing to a pressure-control mode of ventilation or by using a cuffed tracheostomy tube.

The presence of a tracheostomy increases the complexity of care for most patients requiring ventilatory assistance. Caregivers must be taught how to suction, clean and change the tracheostomy tube and how to assess for displacement and obstruction.[105] The presence of a tracheostomy tube interferes with the child's speech and swallowing, increases risk for infection and aspiration and is associated with airway complications such as infection at the stoma site, granuloma formation, tracheal stenosis and traumatic tracheoinnominate or tracheoesophageal fistula formation.[107–109] Although the presence of a tracheostomy alone can increase caregiver stress,[110] in some situations (such as the need for continuous ventilatory assistance and difficulty with secretion management in a young child) it can ease the burden of care. Thus the decision to advance from noninvasive to invasive ventilation must be individualized, considering the impact on both the child and the child's caregivers.

## Options for Ventilatory Support

### Body Ventilators

Initially, negative-pressure body ventilators were used to augment the ventilatory efforts of patients with restrictive lung disease.[102] Devices like the iron lung (tank ventilator), chest shell, poncho and cuirass ventilators can all successfully reverse respiratory failure in children.[102,111,112] Negative-pressure body ventilators, however, are cumbersome and can cause upper airway obstruction.[102,112,113] This may result from phasic collapse of the epiglottis or a lack of preinspiratory upper airway muscle activation before the ventilator supplies a negative-pressure breath.[114,115] Negative-pressure ventilators are difficult to get into and out of; thus they are not well suited for subjects who require frequent access for care. They are not portable, so the user cannot readily travel or sleep at other people's homes. Nevertheless, a negative-pressure ventilator can be an excellent alternative for the patient who cannot tolerate placement of a nasal device or the sensation of nasal positive pressure. Positive-pressure body ventilators, like the pneumobelt, are used to only a limited degree in children. The pneumobelt must be used while the patient is in a seated position so it is not suitable for the treatment of nocturnal hypoventilation.

## Positive-Pressure Devices

The most common way for children to receive ventilatory assistance noninvasively is by positive pressure delivered via nasal, oronasal or mouthpiece interfaces. Application of positive pressure can relieve upper airway obstruction as well as improve minute ventilation and unload inspiratory muscles. The source of positive pressure can be a portable volume- or pressure-preset ventilator, bilevel positive-airway-pressure ($B_i$PAP) device, or continuous positive-airway pressure (CPAP) device. $B_i$PAP and CPAP devices use a blower to generate flow adequate to achieve the desired pressure set by the practitioner. Portable ventilators use pistons or turbines to generate the selected volume or pressure and can do so at lower flow rates. Newer positive-pressure ventilators can also provide continuous flow, which allows for spontaneous breathing without imposing additional work and dead space. In general, $B_i$PAP units are smaller than portable ventilators, but newer portable ventilators generally weigh less than 15 pounds. $B_i$PAP devices operate more quietly, compensate for leaks better and are also less costly than portable ventilators.[116] On the other hand, $B_i$PAP devices cannot generate such high peak pressures and have higher rates of energy consumption than portable ventilators.[117] Unlike portable ventilators, most $B_i$PAP devices do not contain an internal battery. Because they use a single-limb circuit for inspiration and exhalation, they are also more likely to promote rebreathing than systems with a double-limb circuit.

Newer portable ventilators blur some of these distinctions and combine features of standard ventilators with those of $B_i$PAP devices. They can compensate for leaks well and are suitable for noninvasive use. They can also be adapted from “open system” single-limb circuits with passive exhalation valves and leak compensation to “closed-circuit” systems with a mechanical exhalation valve. These machines have an internal battery, the ability to control several ventilation variables and more extensive monitoring capabilities than $B_i$PAP devices.[118]

Some consider that CPAP is not a form of noninvasive ventilation, since the patient receives neither mandatory breaths nor assistance during spontaneous efforts. CPAP can, however, unload respiratory muscles and enhance minute ventilation by relieving upper airway obstruction, offsetting intrinsic PEEP or improving lung compliance. $B_iPAP$ devices provide pressure-support ventilation, in which the patient's spontaneous effort is supported to a preset pressure. The supported breath is initiated by the patient, and the support is cycled off when inspiratory flow falls to a preset percent of peak flow. Many $B_iPAP$ devices have, in addition to a spontaneous mode, timed or combined spontaneous/timed modes in which mandatory breaths can be delivered in the event that the patient's drive or ability to trigger the machine is inadequate. The sensitivity of trigger and cycle variables differs according to the manufacturer,[119,120] making some machines a poor choice to use in infants or patients who are very weak.[121] In such circumstances, the practitioner can set a mandatory rate higher than the child's spontaneous rate to overcome the mechanical shortcomings of the system.[93] When supplemental oxygen is required, the amount bled into the system can mask the patient's inspiratory efforts by contributing additional flow that must be overcome to trigger the device. The final $FiO_2$ delivered to the patient will vary depending not only on the flow rate of oxygen bled into the system but also on where in the circuit the oxygen is introduced and the inspiratory pressure measured.[122] It is unusual to be able to deliver an $FiO_2$ above 0.5–0.7 noninvasively.[122,123]

Older first-generation portable ventilators, which are still in use, are able to provide only volume-preset breaths in which a desired tidal volume is set by the practitioner. The breaths can be delivered in a synchronized intermittent mandatory ventilation (SIMV) mode, where the patient breathes spontaneously but unsupported through the ventilator circuit in between mandatory positive pressure breaths delivered according to a set rate, or in Assist/Control (A/C) mode. Here the practitioner sets a rate at which mandatory breaths are delivered, but if the patient wishes to breathe above that rate, each effort results in a fully supported positive-pressure breath. Such machines also require the use of an external PEEP valve if end-distending pressure is required. When large leaks are present in children with tracheostomies who use this type of ventilator, it is usually not possible to maintain the set PEEP.

Newer second- and third-generation portable ventilators can provide either pressure preset or volume preset breaths, pressure support breaths, and continuous flow. Thus they are more versatile, allowing for more modes of ventilatory support that can enhance ventilator-patient synchrony and hence patient comfort. The PEEP valve is integrated into the machine. These machines can be used to provide CPAP with or without pressure support, SIMV with or without pressure support and A/C ventilation. Both trigger and cycle variables can be adjusted on most models. All have internal batteries that differ widely among models in duration,[124] whereas external lightweight lithium batteries allow for their use away from an electrical power source for several hours.

No single type of positive-pressure device is ideal for all patients. Patient characteristics, as well as machine characteristics like trigger and cycle sensitivities, and sensitivity to leaks, can influence the degree of patient-ventilator dyssynchrony and adequacy of ventilatory assistance.[119–121] Patients who breathe spontaneously will benefit from features like continuous flow and pressure support. Patients with no spontaneous respiratory effort (e.g., children with cervical spinal cord injury) do not require such accessories, and their presence can occasionally be detrimental. When there is a large leak around the child's tracheostomy or interface, the leak will be interpreted by the ventilator as a patient-initiated breath and will result in unintended excessive ventilation or ventilator auto triggering. If trigger or cycle sensitivities are not adequate, the child will make inspiratory efforts that are not supported, or have to exhale while the device continues to provide a positive pressure breath.[125] In the best of circumstances the needs of the patient are matched to the capabilities of the device, and interactions between device and child are assessed critically before the child is given that machine for long-term use.[121]

## Ancillary Equipment

In addition to the actual ventilator, other equipment needs of children requiring chronic mechanical ventilation will vary. This will depend on the interface being used (noninvasive versus tracheostomy), whether or not the child requires assistance with airway clearance and coughing, how many hours the child can tolerate being without ventilator support and whether or not the child spends most waking hours in a wheelchair. In addition, how far the child lives from the medical center or durable medical equipment company and how frequently power outages occur in the child's community are important considerations.

Those children who use nasal or oronasal interfaces should have a second, different style interface available to interchange with the primary one. In this way, different areas of the face are exposed to pressure from the mask, and discomfort or skin injury can be minimized or avoided. Small children, those who perspire excessively and those who have difficulty controlling secretions should have backup headgear available for noninvasive interfaces. Fixation devices for noninvasive interfaces come in a variety of materials and, often because nasal interfaces are used that were designed for adults, straps must be altered or extra hook and loop (Velcro) straps added to fit a child's head and keep the interface in place. Whenever the mask or tubing touches the child's skin, adequate padding must be provided and frequent assessments performed to avoid skin injury. Children with tracheostomies should have a second tracheostomy tube available for emergencies and another tube one size smaller in case there is difficulty reinserting the tube during an unplanned tube change. Children who drool excessively may require extra tracheostomy tube holders to allow for frequent changes so that skin breakdown under the ties can be avoided. Twill tape, Velcro, neoprene and beaded chain tracheostomy holders all are available and are chosen based on patient/family preference and the experience of the health care team. Standards for tracheostomy care in children have been published that detail the equipment required.[105]

Children with neuromuscular weakness develop a stereotypical progression of respiratory involvement that begins with difficulty clearing the central airways of secretions, even before they develop ventilatory insufficiency.[44] Cough is the mechanism primarily responsible for clearing the central airways of secretions and particulate matter, while mucociliary clearance is the chief mechanism by which debris is removed from the peripheral airways.[126] Weakness of inspiratory, bulbar or expiratory muscles can impair effectiveness of coughing and predispose toward chronic atelectasis or recurrent pneumonia.[127]

To address this, several methods have been developed for subjects whose cough is inadequate to clear the central airways. These include techniques such as manual or mechanical insufflation to raise precough lung volume, manually assisted cough, and mechanical exsufflation with negative pressure.[128] Mechanical insufflation/exsufflation (MI-E) combines mechanical insufflation and exsufflation with negative pressure; it has been utilized in patients with inadequate cough since the polio epidemics of the 1940s and 1950s.[129] MI-E has gained increasing popularity in children over the last two decades, and has been used safely across the spectrum of pediatric ages.[130] The device can be used with a face mask, a mouthpiece, or attached directly to a tracheostomy tube. Among 62 patients ranging in age from 3 months to 28.6 years, no correlation existed between the pressures used with MI-E and the age of the patient or the type of underlying neuromuscular disease.[130] Generation of cough peak flows high enough to achieve airway clearance requires a pressure span ($P_{\text{insufflation}} - P_{\text{exsufflation}}$) of at least 30 cm $H_2O$.[131] But during acute illness when increased airway resistance or decreased lung compliance might occur, higher pressures are probably required to achieve adequate precough volumes and cough peak flows.[132] In addition, increasing insufflation time can result in higher exsufflation flows, whereas increasing exsufflation time does not significantly increase expiratory flows.[131,133]

Most studies that evaluate the effectiveness of MI-E in patients with neuromuscular weakness report the short-term results of a single MI-E treatment; there are no randomized controlled trials that evaluate long-term effects like survival, quality of life, duration and number of hospitalizations, or serious side effects of MI-E use.[134] There have, however, been smaller studies that report a reduction in the number of hospital days in the 6 and 12 months following MI-E use compared with a similar period before its use. In addition, improved quality of life for the child and parents was reported resulting from their enhanced ability to manage illnesses or acute episodes of airway obstruction at home, thereby avoiding emergency rooms and hospital visits.[135,136] Serious side effects of MI-E use are only rarely reported in children and include cardiac dysrhythmias, aggravation of gastroesophageal reflux, gastric distention and dynamic central airway collapse.[130,137] Complications related to barotrauma, like pneumothorax, have only rarely been reported in adults[138] and never in children. The author has, however, cared for a 16-year-old boy with Duchenne muscular dystrophy who experienced recurrent pneumothoraces while being treated with both MI-E and positive-pressure ventilation via tracheostomy.

Home mechanical ventilators are generally reliable pieces of equipment, but the addition of microprocessor technology and increased complexity of the machines increases the risk for ventilator malfunction. In a survey of 150 ventilator users followed over 1 year, of whom 44 were 18 years of age or younger, defective equipment or failure of mostly first-generation ventilators occurred on average of only once per 1.25 years of continuous ventilator use.[139] Of the 189 incidents of suspected ventilator failure, actual equipment malfunction or failure was responsible for the report in only 73 (39%). Two patients required rehospitalization, and in both cases, the problem was due to a change in the patient's condition that mimicked equipment failure rather than a true ventilator malfunction. King accessed the FDA Manufacturer and User Facility Device Experience (MAUDE) database, which reported more than 150 home mechanical ventilation failures or malfunctions in the United States in 2010.[29] In a recent European review of ventilator problems among both pediatric and adult home ventilator users, the likelihood of ventilator malfunction was fairly small (involving 28% of more than 3000 calls received over a 6-month period).[140] The risk of ventilator malfunction was greater if the machine was more than 8 years old, if it was a model newly introduced to the market or if it was used 16 hours/day or more.[140] Given these considerations, if a child cannot tolerate absence of ventilatory support for more than 4 hours of the day[35] or if the child lives more than 1 hour from the tertiary care center or home equipment company,[139] the child should have a second ventilator and complete circuit setup in the home in case of emergency. If the child spends most of the day in a wheelchair, two setups are usually made available: one left on the chair for daytime use and a second kept at the bedside. To assure proper functioning, mechanical ventilators and other equipment should undergo a routine check at least monthly and receive preventive maintenance as needed.[35] These checks should include not only assessment of various ventilator functions (i.e., inspiratory and expiratory pressures, trigger sensitivity, oxygen delivery, alarms, etc.) but also of whether the actual settings match the patient's prescription.[141]

Most of the newer ventilators designed for home use have an internal battery that can be used during transfers or a brief power outage. In some models, the internal battery lasts only about 1 hour, depending on the amount and mode of support required by the child.[124,142] External batteries are necessary when the child is expected to spend longer away from an electrical power source. These periods can last up to 12 hours, again depending on the child's ventilator requirements.[142] Some systems also permit the ventilator to use power from the battery of an electric wheelchair to reduce the bulk of equipment that must be transported. Batteries enhance the child's portability and can be used in emergencies when electrical power is not available. If the child lives in an area where electrical power outages are frequent, a backup generator may be required to keep the child safely at home during outages and to run other equipment such as suction machines and monitors.

Infants and children who are supported by mechanical ventilation via tracheostomy require humidification of the ventilator circuit, since bypassing the natural upper airway results in delivery of cool, dry air to the central airways. This can result in ineffective secretion clearance and plugging of the artificial airway. Inspired gas should be humidified to 28–35 mg/L, and heated to 29–35°C.[105,143] This can be achieved with heated humidifiers or heat-moisture exchangers. The effectiveness of heat-moisture exchangers varies by manufacturer,[144] and their efficiency decreases with increasing tidal volume, inspiratory flow, and minute ventilation.[143] Heat-moisture exchangers are not as efficient as heated humidifiers when used in infants and small children and should be confined to use during travel or waking hours, with a heated humidifier used during sleep. The addition of heating devices to the ventilator circuit can increase ventilatory demands: heated humidifiers increase ventilator circuit compliance, and heat-moisture exchangers add dead space to the circuit. In both cases, the set tidal volume may have to be increased to accommodate these changes. Children who use noninvasive ventilation do not necessarily require humidification of the circuit. Patients who complain about nasal congestion or dryness, however, can benefit from humidification and they are often more comfortable when the delivered air is humidified.

Patients ventilated via tracheostomy and those with neuromuscular or neurologic conditions using noninvasive ventilation require suction equipment. Both stationary and portable devices should be available to facilitate patient mobility.[78] Portable suction machines are capable of developing pressures in excess of the 60–150 torr recommended for airway suctioning.[145] All patients with tracheostomies and those who use noninvasive ventilation to treat alveolar hypoventilation require a manual ventilation system (e.g., self-inflating resuscitation bag) for use with suctioning or during emergencies. The self-inflating bag can also be used for lung volume recruitment in patients with neuromuscular weakness.[89,90] Patients with impaired cough also can use a self-inflating bag to provide insufflation before manually assisted cough, or use specialized equipment (e.g., a mechanical in-exsufflator) to aid with airway clearance.[78]

Home positive-pressure mechanical ventilators have internal alarms, as do many newer $B_i$PAP machines. These include alarms for low pressure or patient disconnect, power failure, low battery, high pressure, apnea, low minute volume, and low tidal volume. These alarms provide early warning in the case of machine failure, ventilator disconnection, inadvertent decannulation, tracheostomy tube obstruction or excessive leak of a noninvasive circuit. The low-pressure alarm present on ventilators delivering positive pressure via tracheostomy is typically set 5 cm below the desired peak pressure to be delivered.[35] However, the low-pressure alarm might not sound in the setting of an inadvertent decannulation when used with children who require small tracheostomy tubes (<4.5-mm inside diameter) because of the high resistance of the tube.[146] For this reason, additional monitoring with external devices is used for the early detection of emergencies.

The use of external monitors remains driven by practice, not data. No author advocates recreating an ICU environment at home, but considerable differences of opinion exist regarding the roles of home cardiorespiratory impedance monitoring, pulse oximetry, and capnometry.[3,4,35,78,147,148] Monitoring practice also varies depending on the method of ventilatory assistance between tracheostomy-delivered, noninvasive positive pressure, and negative-pressure ventilation.[13] Impedance monitors are advocated generally by some[4,148] or recommended for use in certain circumstances, such as in the child who requires a tracheostomy tube smaller than 4.5 mm.[35] Others feel that such monitoring is both redundant and unnecessary.[147] Importantly, the cardiorespiratory monitor will not alarm in the event of a tube obstruction, inadvertent decannulation or ventilator disconnection until the child has become sufficiently hypoxemic to experience bradycardia. Pulse oximetry monitoring is not universally advocated,[147,148] but a recent clinical practice guideline on pediatric home mechanical ventilation from the American Thoracic Society recommends the use of pulse oximetry instead of a cardiorespiratory monitoring device for children who are invasively ventilated, especially when asleep or unobserved.[72] A decrease in the number of deaths and cases of severe hypoxic encephalopathy related to airway accidents has been attributed to this approach,[9] as oximetry will detect hypoxemia associated with ventilator failure, tube obstruction, or accidental disconnection sooner than these events can be discovered by cardiorespiratory monitoring. Pulse oximetry is also used to assist in weaning supplemental oxygen or ventilator support and as an early warning of lower respiratory tract complications (such as bronchospasm or infection) that might require an increase in ventilatory support. Pulse oximetry monitoring is an integral component for monitoring patients with neuromuscular disease, where hypoxemia heralds the need for increased airway clearance, or delay in airway extubation to noninvasive ventilatory support after an acute illness.[93] Importantly, absence of nocturnal hypoxemia by pulse oximetry monitoring does not preclude significant episodes of hypercapnia in children who require nocturnal ventilation for treatment of alveolar hypoventilation.[149] Capnometry or capnography is not advocated by all,[147] but its intermittent use can be helpful in assessing a child's ability to sustain adequate ventilation during weaning trials. Continuous capnography or capnometry is not indicated for home monitoring. Recently a transcutaneous oximeter/capnometer was shown to be accurate and effective in assessing gas exchange in children with chronic respiratory failure using noninvasive ventilation at home.[149]

In general the recommendation for external monitoring must be individualized. Although such monitoring can be lifesaving, the monitors themselves can also increase caregiver stress and anxiety.[110] False alarms can disrupt parents' sleep, contributing to caregiver sleep deprivation.[76,150] No monitoring system can fully replace direct patient observation,[151] and none of the external monitors should be considered as a surrogate for appropriate ventilator alarms.

## Patient Follow-Up

The course of children with chronic respiratory failure is either one of gradual improvement with ability to be liberated from mechanical ventilation or a trajectory of worsening, depending largely on the natural history of the underlying disease. The frequency with which children need to be seen will vary according to where they are in their disease process and the comfort of the health care team and family to perform interventions at home. For instance, an adolescent with type 2 SMA might require only semiannual visits, once growth has stopped, if the progression of the underlying disease is slow. An infant with type 1 SMA is likely to require visits every 2–3 months to reassess the adequacy of ventilation and airway clearance.

Growth and stamina for play or developmental activities are key determinants of adequacy of ventilatory support for children with chronic respiratory failure. Yet nutritional assessments in this population often do not take into account the metabolic state of the patient, resulting in undernutrition or overnutrition.[152] A recent study of 20 children ventilated at home via tracheostomy showed that 35% had mild to moderate undernutrition while 13 of 19 were either overfed or underfed.[153] Furthermore, 11 of 19 received less than the daily recommended protein intake. In addition, 45% were hypermetabolic, while 30% were hypometabolic. These findings highlight the need for expert nutritional input and assessment to evaluate the needs of ventilator-dependent children who often have complex conditions and who are at risk for malnutrition.

Children with chronic respiratory failure can be weaned partially or completely from mechanical ventilation in postacute rehabilitation facilities[41,42] or in the home.[154,155] In our practice, once a child has demonstrated tolerance for reduction in ventilator support during an office visit, the family is given guidelines for reduction in support and clinical indicators for tolerance of reduction of support. Through weekly telephone interviews, changes in vital signs, weight gain, tolerance for physical activity, and overall mood are assessed, and if the child tolerates the reduction in support, orders are given for a continued slow reduction of ventilator assistance. Often, several days of reduction of mechanical ventilation are required before intolerance becomes apparent, either through an alteration in mood, reduction of activity, or failure to continue to gain weight. Thus reductions occur only weekly or at most twice weekly. A 20% increase in heart rate or respiratory rate from the resting condition or failure to maintain adequate gas exchange as determined by oximetry and capnometry are indicators to curtail further weaning immediately. There is no single best way to liberate a child from mechanical ventilation. Some programs use polysomnography to guide nocturnal weaning of mechanical ventilation[155] whereas others do not.[154] Some practitioners gradually reduce the level of pressure support or number of mandatory breaths delivered to the patient. Our practice usually is to begin weaning trials either to CPAP or complete nonsupport for short periods once or twice a day, returning the child to the usual level of support for the duration of the day. The weaning trials are gradually lengthened as tolerated while the child is awake until the child is breathing independently for all waking hours. Further reduction of support then occurs during naps and finally during sleeping hours overnight. The ability to liberate a child from daytime mechanical ventilation, even if nocturnal support is still required, minimizes the need for community health services and promotes school attendance.[156]

If a child had undergone tracheostomy placement to facilitate chronic mechanical ventilation and has weaned from ventilator support, decannulation of the trachea should be considered. There is no single best approach to tracheal decannulation. Most authors recommend bronchoscopy before attempted decannulation to assess for airway obstruction from granulation tissue, suprastomal collapse, tracheomalacia, enlarged tonsils or adenoids or vocal cord paralysis.[154,157–159] Once airway patency is assured, the tube is often downsized and capped for a period of time,[158–160] whereas other authors simply remove the tube.[161] Other programs remove the tracheostomy tube only in the sleep laboratory with overnight polysomnography to assure adequate nocturnal ventilation.[162] In all cases, however, the child is hospitalized for 24–48 hours to be certain that airway compromise does not develop after tube removal. Polysomnography with the tube downsized and capped can be used as an adjunct when concern about patency of the airway during sleep affects the decision to decannulate the airway.[160] In each case, the approach to tracheal decannulation should be tailored to the individual's condition.[158]

Children with tracheostomies require routine tube changes. Recommendations, based on practice rather than evidence, range from daily to monthly with most experts suggesting a weekly timetable.[105] However, a panel of experts in otolaryngology failed to reach consensus on the proper interval for tracheostomy tube changes.[163] More frequent changes may be required in the setting of an acute infection, when thick secretions can obstruct the tube. Bacterial colonization of the airway is almost ubiquitous in patients with tracheostomies,[164] but most experts do not advocate the routine use of oral or inhaled antibiotics for prophylaxis against pneumonia.[165] Although *Pseudomonas aeruginosa* and *Staphylococcus aureus* are the two most commonly isolated organisms from patients on long-term mechanical ventilation, anaerobes may also play an important role and should be considered when antibiotic treatment is contemplated.[166] Routine bronchoscopic evaluation to assess for airway lesions or narrowing and appropriate sizing of the tube is recommended every 6–12 months or more frequently in a child experiencing rapid changes in growth or medical condition.[105] However, in the absence of bleeding or difficulty with tracheostomy tube changes, some otolaryngologists do not perform routine bronchoscopic evaluation.

Infants and toddlers with BPD experience exacerbations of respiratory failure most commonly because of acute wheezing illnesses and nonbacterial respiratory infections. During such episodes, ventilatory support may have to be increased. The first intervention for respiratory distress in a child with a tracheostomy is to perform a tracheostomy tube change so as to ensure that there is not partial obstruction of the tube causing the distress. Occasionally, antibiotics are administered when tracheal secretions remain purulent, increased neutrophils are identified on sputum Gram stain, and a predominant bacterial organism is recovered from the sputum culture.[165] Thereafter, if minor changes in ventilator support do not correct gas-exchange abnormalities or if the family or skilled caregivers are not comfortable with continuing care at home, the child should be hospitalized.

Patients with neuromuscular weakness can experience acute deterioration in respiratory function when impaired mucus clearance leads to atelectasis or respiratory infections cause increased mucus production with airway obstruction. The first intervention is to increase airway clearance to resolve the obstruction or to keep pace with increased mucus production. Experts also recommend judicious use of antibiotics for respiratory infections,[55] even when the illness begins as a viral infection, because stasis of mucus predisposes to secondary bacterial infections. Patients supported by NIV may require longer (up to continuous) periods of ventilatory support during the acute illness, or an increase in applied positive pressure. Distending pressure (expiratory positive airway pressure [EPAP]) is often increased to overcome atelectasis, while inspiratory positive airway pressure (IPAP) may have to be increased to offset increases in airways resistance or a decrease in lung compliance. If the child requires airway intubation for an acute illness, some experts advocate waiting until the child has weaned from supplemental oxygen before attempting extubation to noninvasive support.[93] Progression of the underlying neuromuscular disease can lead to inadequate support, so symptoms of sleep-related hypoventilation should be sought at each office encounter and reassessment of ventilatory requirements during sleep should occur at least annually.[167]

# Outcomes

## Weaning From Ventilator Support

The underlying cause of respiratory failure is the principal determinant of whether a child will eventually be liberated from ventilator support.[3,4,41,156,168–171] Several studies suggest that those children receiving long-term mechanical ventilation for parenchymal lung disease such as bronchopulmonary dysplasia or central airway lesions like tracheomalacia are more likely to be able to be weaned from mechanical ventilation than are those with neuromuscular weakness or multiple congenital anomalies.[3,41,156,168,169,171] This finding probably reflects the propensity for improvement in a child's lung mechanics or respiratory pump function over time in the former group and deterioration in lung and respiratory pump function in the latter. In a series of 102 patients with BPD supported by home mechanical ventilation via tracheostomy, 69 (83% of survivors) were liberated from mechanical ventilation, and 97% of those children were liberated by 5 years of age[172]; 58 of 60 children who could be decannulated accomplished that before 6 years of age. In contrast, among 449 children supported with long-term NIV, only 42 (9%) were liberated over 18 years[173]; 60% of the population had neuromuscular or chest wall disease. One of these reviews, in which 20% of the 228-patient cohort carried a diagnosis of central hypoventilation syndrome, included transitioning from chronic mechanical ventilation to diaphragm pacing as a reflection of successful weaning.[169] Severity of underlying disease also may influence weaning outcome: of 35 children requiring chronic mechanical ventilation via tracheostomy in association with congenital heart disease, only those patients with less severe underlying disease, as reflected by a Risk Adjustment for Congenital Heart Surgery (RACHS-1) score ≤3, were able to wean from mechanical ventilation.[170]

## Survival

There is no question that chronic ventilatory support, even when confined to nocturnal use alone, improves survival among patients with neuromuscular and other restrictive chest wall diseases. In the absence of ventilatory support, mean duration of survival for patients with Duchenne muscular dystrophy and diurnal hypercapnia was 9.7 months.[174] In contrast, among 23 young men with Duchenne muscular dystrophy and diurnal hypercapnia who began NIV, survival was 85% at one year and 73% at 5 years.[83] Because of the increased longevity of patients with diseases such as Duchenne muscular dystrophy resulting from improved respiratory care and other technologies, new complications and medical issues are being described that will require greater recognition and surveillance.[173,175,176] In addition, the success of home ventilation in prolonging survival of ventilator-dependent children with little likelihood of weaning from support highlights the need to create adult-care transition programs for these patients as they reach the age of majority.[32,173,177,178]

Among all children with chronic respiratory failure cared for at home, mortality is generally low; the greatest predictor of long-term survival is the prognosis of the underlying condition.[179] Teague abstracted the average 5-year cumulative survival from published reports of 265 pediatric patients and reported approximately 85% survival in children treated with home mechanical ventilation between 1983 and 1998.[179] Of the 137 patients with neuromuscular diseases who were receiving home mechanical ventilation, the 5-year cumulative survival estimate was 75%. A single-center experience from Canada involving 379 children followed between 1991 and 2011 described an annual mortality rate of only 0.73%.[32] Once again, severity of the underlying disease has been suggested as a predictor of survival in some diseases: the cumulative 5 year survival of children with chronic respiratory failure associated with congenital heart disease was 68%, but it was 90% when considering only those with a RACHS-1 score of ≤3 and 12% for those with a score ≥4.[170]

Most studies suggest that the primary cause of death of ventilator-dependent children cared for outside hospital relates to progression of the underlying disease.[8,171,179,180] A recent single-center review, however, noted that death among tracheostomy and ventilator-dependent children was often unexpected and may have been related to comorbidities as well.[169] Similarly, comorbidities contributed to mortality in children supported with long-term NIV.[173] Although it is unlikely for ventilator malfunction to be the cause of death,[181] one series in which 17 patients died over a 20-year period described 3 deaths resulting from unwitnessed ventilator disconnections and 1 from an overnight power failure of a negative-pressure body ventilator. This led the author to speculate that at least 3 and perhaps as many as 7 deaths could have been prevented if the patients had been monitored visually or electronically.[10]

The presence of a tracheostomy increases the risk of death as well as other negative outcomes. Edwards et al. calculated that tracheostomy-related deaths accounted for 8% of all reported deaths among published accounts.[169] In their cohort, tracheostomy-related deaths were responsible for 19% of all deaths, with complications that included obstruction of the tube, bleeding from tracheal granulomas and misplacement of the tracheostomy tube into a false track. Downes and Pilmer compared the incidence of life-threatening tracheostomy-related accidents between those ventilator-dependent children cared for in the home and those in the hospital in the early 1980s.[9] Although the rate was low, they found it to be 9 times greater among those cared for at home (2.3 of 10,000 patient days) versus the pediatric ICU (0.3 of 10,000 patient days). The authors speculate that the recent use of home pulse oximetry helped to reduce the disparity. Tracheostomy-related deaths have also been reported after children had already been weaned from chronic mechanical ventilation. Of 30 deaths among 101 infants with chronic respiratory failure over an 18-year period, 10 occurred after ventilation had been discontinued.[8] Six of the deaths were considered airway-related accidents, and all but one occurred following hospital discharge.

## Quality of Life

When surveyed, ventilator-dependent children generally view the use of the ventilator as positive, because it helps them breathe more easily, giving them more energy and an overall sense of better health.[182,183] Mechanical ventilatory support is associated with a reduction in hospital admission frequency, improved sleep quality, and better daytime functioning in children with nocturnal hypoventilation from neuromuscular and chest wall disorders.[184–186] Subjects who have diurnal hypercapnia or who complain of dyspnea by the end of the day experience relief of dyspnea by using daytime mechanical ventilator support for as little as 2 hours in the afternoon.[54] When patients were surveyed, quality of life of those with neuromuscular disease was independent of the need for mechanical ventilation.[187] Ventilator users have a generally positive outlook and are interested in making plans.[186,188–190] Ventilator-dependent children attend school, including college and graduate school, and vacation with their families.[186,189] They are generally happy with how they spend their time, although adolescents with chronic respiratory failure may be less satisfied with their daily activities than younger children.[189] Children dependent on mechanical ventilation view their equipment as adaptive technology, in much the same way that a wheelchair helps with mobility.[182] Nevertheless, children who are ventilator users feel ostracized by people outside of immediate circle of friends and family because of their need for breathing support,[75,182,183] and they express a concern for being excluded from society and everyday relationships with others.[191] Both they and their families express feelings of isolation because of the disability,[75] and siblings feel that they have to shoulder more adult responsibilities.[191]

In fact, there is disparity between the perceived good quality of life of ventilator-dependent children and that of their families. Home care of a ventilator-dependent child is stressful, and the degree of stress increases with duration of care.[75,190,192,193] Parents focus more on the possibility of their child's death and dying than do the ventilator users themselves.[75,182] One single-center study found that whereas parents of ventilator-dependent children rated their children's quality of life higher than did parents of children dependent on gastrostomy tubes, parents of both groups rated their children's health quality of life lower than that of healthy children and children with other complex conditions like cystic fibrosis.[194] Additionally, home care of ventilator-dependent children adversely affects the health of caregivers, resulting in sleep disruption and inadequate amounts of sleep, feelings of depression and being overwhelmed, as well as limited time for the caregiver to pursue health-promoting activities.[76,192,195,196] Nevertheless, parents typically express a desire to have their child at home and satisfaction with their choice to do so.[75,77] Regardless of these stresses, parents and ventilator users themselves typically rate the child's quality of life higher than do health professionals,[24,197] and recognition of this by parents adds to their sense of frustration and isolation.[75,182]

## Summary

The number of children requiring prolonged mechanical ventilatory support continues to grow because of improved care of critically ill neonates, infants, and children; advances in medical technology and changing practices regarding children with neuromuscular diseases. Whereas negative-pressure body ventilators gave way to positive-pressure ventilation via tracheostomy in the 1970s and 1980s, recent trends have been toward noninvasive positive pressure ventilation. Significant improvement in equipment, monitoring and understanding of the pathophysiology of respiratory failure has led to a wider array of therapeutic options that benefit patient tolerance. Significant challenges remain, especially concerning the design of interfaces and equipment for very young patients, supporting patients and their families to avoid caregiver fatigue and improving general societal access. This includes access to public transportation, housing choices (e.g., group homes for ventilator-assisted individuals), and employment opportunities. Older children who remain ventilator-dependent will require programs designed to transition their care to adult care providers.

# Microbiological Diagnosis of Respiratory Illness

## Recent Advances

*David R. Murdoch MD, MSc, DTM&H, FRACP, FRCPA, FFSc(RCPA), Anja M. Werno MD, PhD, FRCPA, Lance C. Jennings MSc, PhD, MRCPath, FFSc(RCPA)*

Infections of the respiratory tract are among the most common health problems in children worldwide, and are associated with substantial morbidity and mortality.[1] A wide variety of microorganisms are potential respiratory pathogens; knowledge about the likely etiologic agents of respiratory infections can help direct management and can also play an important role in disease surveillance. Beyond the identification of specific pathogens, the clinical microbiology laboratory can also provide valuable information on antimicrobial susceptibility and strain typing. Continued liaison between clinicians and laboratory staff is vital to facilitate the most cost-effective use of laboratory diagnostics.

Presently, we are still reliant on many traditional diagnostic tools that have been used for decades to determine the microbial etiology of respiratory infections.[2,3] However, these tools have been increasingly supplemented by newer methods, particular molecular diagnostic techniques, which have enabled the more rapid detection of many pathogens that were previously difficult to detect.[4] These advances have particularly led to improvements in the ability to detect respiratory viruses and other microorganisms that do not normally colonize the respiratory tract. Moreover, recent discussions about the existence of a lung microbiome have challenged traditional paradigms about the pathogenesis of respiratory infections.[5,6] The concept that the healthy lung may not be a sterile organ is reshaping our interpretation of laboratory diagnostics.

This chapter focuses on the use of the clinical microbiology laboratory to determine the microbial causes of respiratory infections in children. Diagnostic aspects of some specific respiratory infections, such as tuberculosis and pertussis, are also covered in other chapters.

# Respiratory Pathogens and Syndromes

Tables 22.1–22.17 show the etiologic agents associated with respiratory infections broken down by respiratory syndrome. These lists represent our current understanding and have changed little over recent decades; there have been only a relatively small number of newly discovered pathogens. The latter include human bocavirus, human metapneumovirus, and a variety of coronaviruses (SARS-CoV, CoV-NL63, CoV-HKU1 and MERS-CoV).[7] Pathogen discovery efforts using unbiased next-generation sequencing methods have shown considerable promise but have not yet identified major new respiratory pathogens.[8,9]

## Table 22.1

**Etiologic Agents Associated With Pharyngitis**

| Viral | Bacterial | Fungal |
|---|---|---|
| Adenoviruses | *Streptococcus pyogenes* | *Candida* species |
| Coronaviruses | Other β-hemolytic streptococci | |
| Parainfluenza viruses | *Corynebacterium diphtheriae* | |
| | | |

| | | |
|---|---|---|
| Respiratory syncytial virus | *Corynebacterium ulcerans* | |
| Human metapneumovirus | *Arcanobacterium haemolyticum* | |
| Rhinoviruses | *Neisseria gonorrheae* | |
| Influenza viruses | Mixed anaerobes | |
| Epstein-Barr virus | *Treponema pallidum* | |
| Enteroviruses | *Chlamydophila pneumoniae* | |
| Herpes simplex viruses | *Mycoplasma pneumoniae* | |
| Measles | *Streptobacillus moniliformis* | |
| Rubella | | |
| Cytomegalovirus | | |
| HIV | | |

*HIV,* Human immunodeficiency virus.

## Table 22.2

### Etiologic Agents Associated With Croup

| **Viral** | **Bacterial** |
|---|---|
| Parainfluenza viruses | *Mycoplasma pneumoniae* |
| Influenza viruses | |
| Respiratory syncytial virus | |
| Human metapneumovirus | |
| Coronaviruses | |
| Human bocavirus | |
| Adenoviruses | |
| Measles | |
| Rhinoviruses | |
| Enteroviruses | |
| Herpes simplex viruses | |

## Table 22.3

### Etiologic Agents Associated With Sinusitis

| **Viral** | **Bacterial** | **Fungal** |
|---|---|---|
| Rhinoviruses | *Haemophilus influenzae* | *Aspergillus* species |
| Influenza viruses | *Streptococcus pneumoniae* | *Alternaria* species |
| Parainfluenza viruses | Anaerobes | *Penicillium* species |
| Adenoviruses | *Moraxella catarrhalis* | Zygomycetes |
| | *Staphylococcus aureus* | |
| | *Streptococcus pyogenes* | |
| | *Mycoplasma pneumoniae* | |

## Table 22.4

### Etiologic Agents Associated With Acute Bronchitis

| **Viral** | **Bacterial** |
|---|---|

| | |
|---|---|
| Adenoviruses | *Mycoplasma pneumoniae* |
| Influenza viruses | *Bordetella pertussis* |
| Parainfluenza viruses | *Bordetella parapertussis* |
| Respiratory syncytial virus | *Chlamydophila pneumoniae* |
| Rhinoviruses | *Haemophilus influenzae* |
| Coronaviruses | *Streptococcus pneumoniae* |
| Human metapneumovirus | *Moraxella catarrhalis* |
| Herpes simplex viruses | *Streptococcus pyogenes* |
| Enteroviruses | |
| Measles | |
| Mumps | |
| Human bocavirus | |

## Table 22.5

### Etiologic Agents Associated With Bronchiolitis

| **Viral** | **Bacterial** |
|---|---|
| Respiratory syncytial virus | *Mycoplasma pneumoniae* |
| Parainfluenza viruses | |
| Adenoviruses | |
| Influenza viruses | |
| Human metapneumovirus | |
| Rhinoviruses | |
| Enteroviruses | |
| Mumps | |
| Herpes simplex viruses | |

## Table 22.6

### Etiologic Agents Associated With Pneumonia

| **Viral** | **Bacterial** | **Fungal** |
|---|---|---|
| Respiratory syncytial virus | *Streptococcus pneumoniae* | *Pneumocystis jiroveci* |
| Parainfluenza viruses | *Haemophilus influenzae* | *Aspergillus* species |
| Influenza viruses | *Staphylococcus aureus* | Zygomycetes |
| Coronaviruses | *Mycoplasma pneumoniae* | *Coccidioides immitis* |
| Adenoviruses | *Bordetella pertussis* | *Cryptococcus neoformans* |
| Human metapneumovirus | *Legionella* species | *Histoplasma capsulatum* |
| Rhinoviruses | Enterobacteriaceae | |
| Epstein-Barr virus | *Pseudomonas aeruginosa* | |
| Enteroviruses | *Acinetobacter* species | |
| Human bocavirus | Mixed anaerobes | |
| Herpes simplex viruses | *Streptococcus agalactiae* | |
| Varicella zoster virus | *Chlamydophila pneumoniae* | |
| Measles | *Chlamydia psittaci* | |
| Rubella | *Chlamydia trachomatis* | |
| Cytomegalovirus | *Burkholderia pseudomallei* | |
| HIV | *Streptococcus pyogenes* | |
| | *Neisseria meningitidis* | |
| | *Coxiella burnetii* | |

| | | |
|---|---|---|
| | *Mycobacterium* species | |

*HIV*, Human immunodeficiency virus.

## Table 22.10

### Etiologic Agents Associated With Lung Abscess

| **Bacterial** | **Parasitic** |
|---|---|
| *Staphylococcus aureus* | *Entamoeba histolytica* |
| Anaerobes | |
| *Streptococcus pneumoniae* | |
| Other gram-negative bacilli | |
| α-Hemolytic streptococci | |

## Table 22.12

### Respiratory Specimens and Diagnostic Testing

| **Specimen Type** | **Microbiological Investigations** | **Comment** |
|---|---|---|
| Sputum/induced sputum | Microscopy; culture; susceptibilities; DFA; PCR | Provided it is a good-quality specimen, it can be a highly informative specimen; can be difficult to obtain in children |
| Nasopharyngeal aspirate/swab | Microscopy; culture; susceptibilities; DFA; PCR | Most useful in viral infections; requires a skilled operator to obtain specimen; in some ways, it is easier to obtain than a throat swab, because the nares are always accessible |
| Nasal swab | Microscopy; culture; susceptibilities; DFA; PCR | Limited usefulness as it only recovers organisms present in the nasal cavity and not beyond |
| Throat swab | Microscopy; culture; susceptibilities; DFA; PCR | Probably the most representative specimen for disease of the upper respiratory tract; many bacterial pathogens are also common colonizers at various stages of childhood; can be difficult to obtain without child and parent cooperation; may represent organisms present in the nose as well as the oropharynx |
| Endotracheal aspirate | Microscopy; culture; susceptibilities; DFA; PCR | Invasive specimen, but is likely to represent pathogens from the lower respiratory tract; can be contaminated by organisms present in the oropharynx that can make result interpretation difficult |
| Bronchoalveolar lavage fluid | Microscopy; culture; susceptibilities; DFA; PCR | Invasive specimen but is likely to represent pathogens from the lower respiratory tract; can be contaminated by organisms present in the oropharynx, which can make result interpretation difficult |
| Transthoracic needle aspiration | Microscopy; culture; susceptibilities; DFA; PCR | Highly invasive specimen; risk of complications; microbiologically of high value provided the correct area has been biopsied |
| Lung tissue | Microscopy; | Highly invasive specimen; risk of complications; |

| | | |
|---|---|---|
| | culture; susceptibilities; DFA; PCR | microbiologically of high value provided the correct area has been biopsied |
| Pleural fluid | Microscopy; culture; susceptibilities; DFA; PCR | Invasive specimen but is the specimen of choice in a child with empyema |
| Blood cultures | Microscopy; culture; susceptibilities; | Very helpful if positive, but the positivity rate in pneumonia is relatively low |
| Serum/whole blood | Immunoassays; DFA; PCR | Serology per se is of limited value, since a diagnosis is dependent on paired sera that then makes it a retrospective tool; a single high titer can occasionally be obtained in acute disease; PCR on whole blood may be helpful in severe disease to detect viremia, but viremia is generally short lived |
| Urine | Antigen detection tests; microscopy; culture | Antigen detection tests are of limited value in children; pathogen is rarely cultured from urine |

*DFA*, Direct fluorescent antibody; *PCR*, polymerase chain reaction.

## Table 22.13

## Gram Stain Appearance of Bacterial Respiratory Pathogens

| **Pathogen** | **Typical Gram Stain Appearance** | **Likely to Be Significant** |
|---|---|---|
| *Streptococcus pneumoniae* | Gram-positive lancet-shaped diplococci | Predominant pathogen in Gram stain with abundant neutrophils |
| *Staphylococcus aureus* | Gram-positive cocci in clumps | |
| *Haemophilus influenzae* | Small pleomorphic gram negative coccobacilli | |
| *Streptococcus pyogenes* | Gram-positive cocci in chains | |
| *Arcanobacterium haemolyticum* | Gram-positive diphtheroid-shaped bacilli | |
| *Corynebacterium diphtheriae* | Pleomorphic diphtheroid gram-positive bacilli; special stain (Loeffler's methylene blue stain) demonstrates typical club-shaped ends) | |
| *Mycoplasma pneumoniae* | Absence of organisms as they lack a cell wall and cannot be visualized on Gram stain | |

## Table 22.14

### Screening of Respiratory Specimen Quality

| **Specimen** | **Acceptable for Culture** |
|---|---|
| Sputum | <10 SEC/average 10× field |
| Endotracheal aspirate | <10 SEC/average 10× field and bacteria seen in at least 1 of 20 oil |

| | |
|---|---|
| | immersion fields |
| Bronchoalveolar lavage fluid | <1% of cells present are SEC |

*SEC,* Squamous epithelial cells.

This table has been modified from Jorgensen JH, Pfaller MA, Carroll KC, et al. *Manual of Clinical Microbiology*, 11th ed. Washington, DC: American Society of Microbiology; 2015.

## Table 22.16

## Molecular Assays Commonly in Use for the Diagnosis of Respiratory Diseases

| Molecular Assay | Principle | Main Use | Comment |
|---|---|---|---|
| Singleplex PCR | Single DNA or RNA target that is amplified | Can be designed for the detection of any known DNA or RNA sequence | Generally higher sensitivity than multiplex PCR as the targets are not competing |
| Multiplex PCR | Simultaneous amplification of several DNA or RNA targets | Respiratory pathogens; immunocompromised protocols; detection of various pathogens in blood cultures | Wide coverage of pathogens in a single test informs clinical management in a timely manner |
| 16S rRNA sequencing | Amplification of 16S ribosomal RNA followed by sequencing of the product | Used to detect bacterial species in a clinical specimen that has failed to detect pathogens in culture. | Covers a wide range of pathogens listed in accessible sequence databases |
| Next-generation sequencing | Sequencing of a whole bacterial or viral genome or simultaneous sequencing of multiple bacterial or viral genes | Resistance testing and outbreak investigations | Can offer multiple gene sequences simultaneously or whole genome sequencing as well as de novo sequencing; currently, high cost prohibits routine use |

*PCR,* Polymerase chain reaction.

## Table 22.17

### Molecular Terms Commonly Used in Diagnostics

| Molecular Term | Explanation |
|---|---|
| PCR | An in vitro chemical reaction that leads to the synthesis of large quantities of a target nucleic acid sequence. |
| Reverse transcriptase PCR | RNA targets are converted into cDNA that is then amplified. This is needed for the amplification of RNA viruses (most common respiratory viruses). |

| | |
|---|---|
| RT PCR | The target amplification and the detection step occur simultaneously in the same tube. These assays require special thermal cyclers. |
| SNPs | Useful markers of genetic differences between strains, e.g., in outbreak investigations. |
| Target amplification techniques | Copies of a specific target nucleic acid are synthesized, and the products of amplification are detected by specifically designed oligonucleotide primers that bind to the complementary sequence on opposite strands of the double-stranded targets. |
| Signal amplification techniques | The target itself is not amplified; instead, the concentration of labeled molecules attached to the target nucleic acid is increased and measured |

*PCR,* Polymerase chain reaction; *RT,* real-time; *SNPs,* single-nucleotide polymorphisms.

### Normal Respiratory Flora

*Streptococcus* species
  - including *Streptococcus pneumoniae*

*Staphylococcus* species
  - including *Staphylococcus aureus*

*Corynebacterium* species

*Moraxella* species
  - including *Moraxella catarrhalis*

*Neisseria* species
  - including *Neisseria meningitidis*

*Haemophilus* species
  - including *Haemophilus influenzae*

*Cardiobacterium* species

*Kingella* species

*Eikenella corrodens*

In general, upper respiratory infections tend to be monomicrobial and are predominantly caused by viruses, with a few notable exceptions caused by specific bacteria (e.g., acute pharyngitis caused by *Streptococcus pyogenes*). Lower respiratory infections are caused by a wide variety of viral and bacterial pathogens. For pneumonia at least, sequential or concurrent polymicrobial infection may be relatively common, and the exact roles of individual microorganisms and how they interact in this context are still poorly understood.[10,11] The incidence of many respiratory infections follows a cyclical pattern aligned with the typical seasonal transmission of specific pathogens. Secular trends have also been noted for some vaccine-preventable infections, such as those caused by *Streptococcus pneumoniae* and *Haemophilus influenzae* type b, with decreasing burden following the successful implementation of vaccine programs.

# Use of the Clinical Microbiology Laboratory

Before ordering a diagnostic test, it is important to be clear about the key clinical questions and expectations of diagnostic testing. Is knowledge about the cause of a particular respiratory infection important for patient treatment, outbreak management, epidemiological surveillance, or to reassure the clinician or caregiver of the child? It is also important to have an understanding about which specimens to collect, what tests are available, test limitations, and how to interpret results to appropriately integrate the findings into their clinical management.

The most useful specimens for diagnostic testing are those collected directly from the site of infection. Unfortunately, it is not always possible to collect these specimens, and this particularly applies to the lower respiratory tract, which is difficult to access safely in a manner that avoids contamination with colonizing organisms.

When bacteria are isolated from specific body sites, such as a throat swab, nasopharyngeal swab, or sputum, it is important to know which bacteria can be found as commensals or colonizers in the upper respiratory tract and which when found would indicate definitive infection. Table 22.15 outlines microorganisms that are regarded as part of the normal respiratory flora.[12–15] Importantly, given the right conditions, some bacteria that can harmlessly colonize the respiratory tract may also be respiratory pathogens. As will be discussed further in this chapter, several microbiological diagnostic tests employed in the diagnosis of childhood respiratory disease have limited ability to differentiate between colonization and disease and are therefore of limited value when considered in isolation.

## Clinical Specimens for Respiratory Pathogen Diagnosis

Detection of respiratory pathogens is dependent on the type and quality of specimen collected, the timing of collection after the onset of clinical symptoms, the age of the patient, and transportation and storage of the sample before being tested in the laboratory. Ensuring high-quality collection of the right specimens is essential for making an accurate and interpretable laboratory diagnosis.

A range of specimens can be used for identifying the microbial etiology of respiratory infections in children and are shown in Table 22.12. Not all specimens are easily obtainable, and the diagnostic utility varies with each specimen type. The inability to obtain good-quality specimens from the lower respiratory tract is a fundamental problem with pneumonia diagnostics, and obtaining representative and uncontaminated specimens from the lungs is a challenge. Specimens collected by sputum induction or bronchoscopy may be contaminated by normal respiratory flora. Transthoracic needle aspiration is the best technique to obtain specimens from the site of infection in pneumonia, but it is performed in few centers despite a good safety profile.[16]

Specimens should be collected as early as possible in the acute stage of an infection, preferably prior to administration of antimicrobial or antiviral drugs. During this period, higher pathogen concentrations are likely to be present; however, the duration of pathogen shedding depends on the microorganism involved and the severity of the infection and other factors. With uncomplicated influenza virus infections, virus shedding is usually 3 to 5 days following symptom onset; however, this may be extended in severe respiratory disease to 5 to 10 days.[17] Children may also shed for up to 10 days and many weeks in immunocompromised individuals.

## Throat and Nasopharyngeal Specimens

The majority of respiratory tract specimens received in the diagnostic laboratory from children are aspirates or swabs obtained from the upper respiratory tract. Nasopharyngeal aspirates are generally superior to swabs for the detection of respiratory viruses, since large numbers of respiratory epithelial cells are aspirated during the collection process.[18] However, aspirates are more difficult to obtain, especially outside the hospital setting, as they require a specific suction device. A range of commercial swabs are available, which include rayon tipped swabs and polyurethane sponges with wooden, plastic, or wire shafts. The availability of flocked nylon swabs, designed for the collection of respiratory samples, allows for the improved collection and release of respiratory epithelial cells and secretions from both children and adults.[19] Their use for obtaining nasopharyngeal specimens has been shown to have a similar performance to nasopharyngeal aspirates for the detection of common respiratory viruses in children, and the technique is relatively noninvasive.[20]

Nasal or oropharyngeal samples are generally not recommended for routine diagnostic use. The combining of nasal and throat swabs has been trialed in children in hospital and community settings and shown to have a reduced sensitivity.[21] In general, viral loads are higher in the nasopharynx than in the oropharynx, but with some respiratory virus infections, avian influenza H5N1, for example, titers may be highest in the lower respiratory tract. There may also be a higher yield from throat swabs compared to other samples for the detection of *Mycoplasma pneumoniae*.[22]

## Induced Sputum

Culture of sputum specimens is commonly used as part of the evaluation of pneumonia in adults. Despite difficulties with interpretation of results,[3] carefully collected and processed sputum specimens have been shown to be useful in some contexts.[23] Nonetheless, there is still ongoing controversy about the value of routinely examining sputum.[24–28] Furthermore, sputum microscopy and culture are not routinely performed in children due to difficulties in obtaining specimens in this age group who are typically unable to expectorate.[29]

To overcome specimen collection problems, methods such as hypertonic saline nebulization have been used to induce sputum production. Induced sputum is now widely used to investigate lower respiratory infections in immunocompromised adults, especially for diagnosing *Pneumocystis jirovecii* infection,[30] and has also been used to diagnose pneumonia in children from settings with a high prevalence of tuberculosis.[31] However, few studies have collected induced sputum routinely from children with pneumonia. Recent studies of children hospitalized with community-acquired pneumonia from Finland, Kenya, and New Caledonia showed that collection of induced sputum was well tolerated, with a diagnostic yield from culture ranging from 12% to 65% using different interpretative criteria.[32–34]

The most rigorous evaluation of induced sputum for the diagnosis of pneumonia in children was performed as part of the Pneumonia Etiology Research for Child Health (PERCH) study. In this large study, there was no clear evidence that isolation of specific potential pathogens by culture or detection by polymerase chain reaction (PCR) was associated with pneumonia case status.[35,36] In addition, for PCR, there was no evidence that induced sputum provided additional evidence over and above testing a nasopharyngeal specimen.[36] In contrast, a recent longitudinal study from South Africa found that testing of induced sputum in addition to nasopharyngeal swabs provided incremental yield for detection of *Bordetella pertussis* and several respiratory viruses.[37]

## Bronchoscopy Specimens

Although obtaining a lower respiratory sample via bronchoscopy is more invasive than sputum collection and is only available in certain facilities, there are potential advantages in being confident that the sample actually comes from the lower respiratory tract and in the avoidance of upper airway contamination. However, despite best efforts to avoid contamination with normal upper airways flora (including with use of protected specimen brushes), this is often difficult to achieve and must be considered when interpreting routine bacterial culture findings.[38] In practice, the use of bronchoscopy to obtain specimens in the context of childhood respiratory infections is largely restricted to immunocompromised individuals and those with problematic cystic fibrosis or with persistent focally abnormal chest radiographic changes.[39] Bronchoscopy can also have an important role in the diagnosis and management of pediatric pulmonary tuberculosis.[40]

## Endotracheal Aspirates

Despite widespread use, the value of endotracheal aspirates to diagnose the cause of ventilator-associated pneumonia is debatable. Even though quantitative culture methods have been recommended, tracheal aspirate microscopy and culture do not appear to distinguish between infection and colonization.[41] There is also evidence that specimens should be rejected from further processing if no organisms are seen on Gram stain.[42]

## Transthoracic Lung Aspiration

Needle aspiration of an area of suspected pneumonia is theoretically most likely to obtain the ideal clinical specimen for determining microbial etiology of pneumonia. Experience with large numbers of procedures at some locations has demonstrated the good safety profile of this technique. In The Gambia, which has the greatest experience with transthoracic lung aspiration in children, a review of over 500 lung aspirates over 25 years reported complications in six patients (all transient) and no deaths from the procedure.[16] Diagnostic yield with both culture and nucleic acid detection methods is appreciable,[16,43] with about a two-fold increase in yield with nucleic acid detection over culture alone.[43] However, the interpretation of results from highly sensitive molecular diagnostic techniques needs to consider new concepts of the lung microbiome that question whether the lungs are normally sterile. Transthoracic needle aspiration is not indicated for all children with pneumonia and is only appropriate for peripheral lesions confirmed on chest radiography.

## Lung Tissue

The use of lung tissue to determine the microbial etiology of pneumonia is largely restricted to postmortem studies.[44] These are rarely performed on children but may provide valuable information on the causes of fatal cases of pneumonia and can confirm antemortem microbiological diagnoses.

## Blood Specimens

Blood can be collected for culture, serological testing and, occasionally, nucleic acid tests. The yield from blood cultures is enhanced by obtaining adequate specimen volume, collecting the specimen prior to antimicrobial therapy, and avoidance of skin contamination through good phlebotomy technique.[45,46] Although there is good evidence that yield increases with increasing blood volume, the optimal collection volume in children is unclear. One current guideline recommends the collection of 3% to 4% of total patient blood volume in patients weighing less than 12.7 kg and 1.8% to 2.7% in patients weighing greater than 12.8 kg.[47] Anaerobic blood culture is usually unnecessary in children.

## Urine

The main reason to collect urine specimens as part of the workup of respiratory infections in children is to test for specific antigens. For this purpose, the timing of specimen collection in relation to antimicrobial therapy is less important than for urine culture for suspected urinary tract infection. Collection of acute phase urine specimens can be challenging in young children, and a variety of techniques have been deployed to enhance collection in a clinically relevant time frame.

Testing of urine for antimicrobial activity by simple bioassay methods has been a valuable tool for detecting prior antimicrobial administration in epidemiological studies, although the timely collection of urine samples in young children can be challenging.[48]

## Microbiological Tools

### Microscopy

As part of the investigation of respiratory infections, specimens obtained from the lower respiratory tract, pleural space, or abscesses that are sent for bacterial culture are usually examined first by Gram stain microscopy. Microscopy provides information on specimen quality and can provide early clues about the cause of infection. For example, the presence of large numbers of polymorphonuclear leukocytes indicates an inflammatory response, while the presence of bacteria with characteristic morphology may provide an early indication of the culture result and give guidance about treatment. When performed by experienced microscopists, some findings can be very specific. For example, the detection of Gram-positive cocci in clusters in a pleural fluid sample is highly suggestive of *Staphylococcus aureus.* The presence of a predominance of small gram-negative pleomorphic coccobacilli in a good-quality sputum sample is suggestive of infection with *H. influenzae.* Table 22.13 lists the typical Gram stain picture of three commonly found pathogens.

Microscopy is also an important tool to assess the quality of lower respiratory samples, which itself has a large impact on the interpretation of culture results.[49] Specimens from the lower respiratory tract can be contaminated by upper respiratory secretions during collection. Also, a poorly collected “lower respiratory” specimen may be predominantly composed of upper respiratory secretions. Either situation can lead to incorrect interpretations of culture results. To overcome this issue, it is standard practice for diagnostic laboratories to assess the quality of lower respiratory samples before they are cultured. This typically involves assessing the number of squamous epithelial cells (SECs) and polymorphonuclear cells (PMNs) in a Gram-stained smear of the specimen.[50,51] The presence of low numbers of SECs and high numbers of PMNs per low-power field are regarded as being indicative of a high-quality specimen.[52] Conversely, specimens with relatively low numbers of PMNs and high numbers of SECs are likely to represent oropharyngeal contamination and are rejected for routine culture. Detection of a potential pathogen in such a specimen that is contaminated with oropharyngeal flora may represent nothing more than the patient's oropharyngeal microbiota.

Table 22.14 summarizes some commonly used criteria for assessment of lower respiratory specimens. Other rejection criteria have been described that also include the presence of PMNs,[51] and it is the responsibility of the laboratory to have a standard operating procedure that specifies rejection criteria. Although there is a paucity of data from children, quantity of SECs alone was demonstrated to be a useful quality measure for induced sputum from young children with pneumonia.[53] Notable exceptions to sputum rejection criteria are specimens for detection of *Legionella* spp.[54] and *Mycobacterium tuberculosis;* any specimen submitted for investigation of legionellosis or tuberculosis should be processed by the laboratory regardless of the specimen quality.

## Culture

Traditional bacterial culture techniques continue to be a fundamental diagnostic tool in diagnostic laboratories. In contrast, viral culture is now infrequently performed as a routine test, as it is time-consuming, requires a specialist laboratory area and has been largely superseded by molecular diagnostic techniques.

Although most important bacterial pathogens grow on standard laboratory media, such as sheep blood agar, special media environmental conditions are required to optimize the growth of some bacteria. For example, chocolate agar is the usual medium used to isolate *H. influenzae,* an atmosphere of 5% $CO_2$ is required to isolate *S. pneumoniae,* and special media are required for culturing *Legionella* species and *B. pertussis.* As a rule of thumb, it takes most bacterial pathogens 24 to 48 hours to grow in culture, and a further 24 to 48 hours are required to perform antimicrobial susceptibility testing.

The recent availability of matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) has revolutionized the workflow in diagnostic laboratories.[55–57] MALDI-TOF MS allows the rapid identification of cultured microorganisms at a relatively low cost. The identification is based on the generation of mass spectra from whole cell extracts that are then compared to a library of well-characterized protein profiles. Although this method still relies on traditional culture methods to obtain a pure isolate, MALDI-TOF MS provides full identification within minutes, including for all major bacterial respiratory pathogens.[58]

When reporting respiratory tract culture results, which are typically mixed cultures, laboratory scientists will focus on predominant organisms and those known to be important pathogens, such as *S. pyogenes* in throat swabs and *S. pneumoniae* in sputum samples (Fig. 22.1). Background oropharyngeal flora will normally not be worked up or reported in any detail, as this information will not contribute to patient care and, indeed, may give the false impression that they need to be treated.

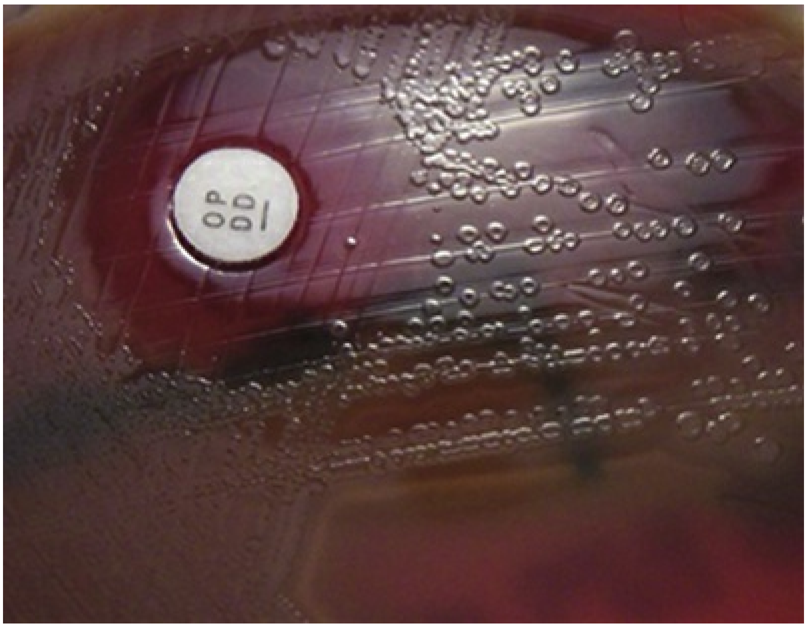

**FIG. 22.1** Typical “draughtsman” phenomenon (ringed colonies with raised edges and depressed centers) and optochin-susceptibility of *Streptococcus pneumoniae*.

The isolation of a bacterial organism from blood conclusively provides evidence of the cause of severe respiratory disease in children. The drawback is that recovery of bacterial pathogens from blood cultures in the context of respiratory infections is very low in children.[59,60] The typical blood culture yield in children admitted to hospital with community-acquired pneumonia is under 10%.[49,61] As discussed previously, the yield is greater when larger volumes of blood are collected, careful measures are taken to avoid skin contamination, and when samples are collected before antibiotics are commenced.[46]

## Antigen Detection Assays

A variety of antigen detection assays for respiratory pathogens have been introduced into routine use by diagnostic laboratories. Direct fluorescent antibody (DFA) assays have been used for many years as rapid tests for respiratory viruses, although they have now been largely replaced by molecular methods or rapid antigen detection tests (RADTs). DFA looks for characteristic fluorescent staining patterns in cellular material from clinical specimens. Currently available assays detect respiratory syncytial virus (RSV), influenza A and B, parainfluenza viruses 1, 2, and 3, human metapneumovirus and adenovirus with sensitivities of about 80% to 90% and very high specificity.[62] DFA requires particular technical expertise but has the advantages that sample quality can be directly evaluated, and test results can be available within 60 minutes.

Among the most common antigen detection assays for respiratory infections are the RADTs for respiratory viruses, particularly influenza viruses and respiratory syncytial virus. The usefulness of RADTs is limited by variable and often suboptimal sensitivity, typically 50% to 98% for RSV and 10% to 85% for influenza viruses, although specificities are generally high (80% to 100%).[63,64] The clinical usefulness of these tests is affected by disease prevalence, being poor when there are few cases in the community (positive predictive value is low and false-positive cases are more likely). During peak virus circulation, although the positive predictive value approaches 100%, the negative predictive value is lower and false-negative results are more likely.[65,66] Due to concerns about poor sensitivity, most authorities recommend that RADTs for influenza are only used with caution outside the influenza season and only when a result will influence patient management; they emphasize that negative RADT results do not exclude influenza in patients with typical signs and symptoms.[67,68]

Other commonly used antigen detection assays for respiratory infections are those that detect *S. pneumoniae* and *Legionella pneumophila* serogroup 1 antigens in urine. These assays, typically in immunochromatographic test format, provide results within a short time frame, but are almost exclusively used on adults with suspected pneumonia. The specificity of currently used pneumococcal urinary antigen tests in children is poor, with frequent false positives due to nasopharyngeal carriage of *S. pneumoniae.*[69–71] This has limited the clinical utility of this test in children, but there may be some value as a diagnostic adjunct in cases with radiologically confirmed pneumonia. There is considerable interest in the development of serotype-specific pneumococcal urinary antigen tests.[72–74] Early assessments in children indicate that these next-generation assays may have some diagnostic value, at least in epidemiological studies, but assay cutoffs need to differ from adults to distinguish between carriage and disease.[75] Pneumococcal antigen detection assays have also been successfully applied to pleural fluid samples in children with pleural effusion or empyema.[76,77] A positive test result has high specificity in this context.

RADTs are also available for the diagnosis of *S. pyogenes* in throat swab specimens. These tests have high specificity for detection of *S. pyogenes*, but have relatively low sensitivity (70% to 90%), which is even lower in those with less severe disease.[78] As a consequence of suboptimal sensitivity, it is commonly recommended to perform bacterial culture on any samples that test negative by RADTs.[79,80]

## Serology

Serological testing for respiratory pathogens was commonly performed in the past, relying either on the detection of immunoglobulin M (IgM) in the acute phase of the disease or the demonstration of seroconversion. More recently, the use of serological testing has largely been replaced by molecular-based assays that provide a rapid diagnosis with greater sensitivity and specificity.

Serological assays still have a limited place in the diagnosis of childhood respiratory disease. Detection of IgM antibodies is still a routine diagnostic tool for *M. pneumoniae* infection. However, older children may not mount an IgM response because of reinfection rather than primary infection, and IgM antibodies may persist for months after the acute infection.[81,82] For detection of *B. pertussis* infection, IgG antibody responses to pertussis toxin may be an indicator of infection, although these assays cannot differentiate between an immune response induced by infection and that due to vaccination. Serological diagnosis of pertussis has largely been replaced by molecular-based assays.[83,84] The serological diagnosis of *Chlamydophila pneumoniae* infection is complicated by the lack of species-specific tests and the resultant potential of cross-reactions in the assay. A single positive IgM response in any disease investigation may represent possible cross-reactivity or nonspecific interference in the assay and needs to be interpreted with caution and in the context of the clinical presentation.

Although detection of antistreptolysin O (ASO) and deoxyribonuclease (DNase) antibodies can be used when investigating the potential complications of *S. pyogenes* infections, such as glomerulonephritis and rheumatic fever, they are not useful for the diagnosis of acute *S. pyogenes* pharyngitis.[85]

## Molecular Methods

The development and implementation of molecular methods is the single biggest recent advance in the diagnostics of respiratory infections.[4] While nucleic acid detection tests (NATs), such as PCR, have been used to detect respiratory pathogens for over two decades, the widespread adoption of these tests by diagnostic laboratories has occurred only recently, largely due to the increased availability of commercial assays. Table 22.16 discusses some of the more commonly used molecular assays, and Table 22.17 gives explanation of commonly used terms in molecular diagnostics.

NATs have several advantages over other diagnostic tools, including rapid turnaround time, the ability to detect low levels of all known pathogens, the lack of dependence on the viability of the target microorganism, little influence of antimicrobial therapy on diagnostic sensitivity, and the ability to be automated.[4] NATs may also provide additional information, such as antimicrobial susceptibility data and strain typing.

For the diagnosis of respiratory infections, the most widely used NATs are those that detect respiratory viruses and noncolonizing bacteria (e.g., *M. pneumoniae, Legionella* species, *B. pertussis*). For these microorganisms, detection in a respiratory sample from a child with a compatible clinical syndrome is regarded as sufficient evidence to assign causation. In contrast, NATs for other bacteria that may also be found in normal respiratory flora, including some of the most important pneumonia pathogens (e.g., *S. pneumoniae, H. influenzae,* and *S. aureus*), have struggled for a role outside research laboratories. As with culture-based methods, the problem with detection of these targets by NAT is the inability to distinguish colonization and carriage from disease.

NATs have particularly revolutionized the diagnosis of viral respiratory tract infections,[86,87] and are now the testing method of choice. Respiratory viruses are now commonly detected by large multiplex panels that typically include influenza A and B viruses, respiratory syncytial virus, parainfluenza viruses, human metapneumovirus, human rhinoviruses, enteroviruses, parechovirus, adenoviruses, human bocavirus, and several coronaviruses (OC43, 229E, NL63, HKU1). There are now many commercial multiplex assays available in a variety of formats, and the landscape is continually changing. In the right clinical context, the detection of a respiratory virus in a respiratory sample is generally regarded as being sufficient to assign causation.[88] However, this assumption is not always reliable as there is uncertainty about the pathogenic role of some viruses,[89] leading some to question the wisdom of using large multiplex NAT panels as first-line tests for respiratory pathogens, given potential problems with interpretation of positive results.[90] Furthermore, respiratory viruses are often detected in a similar proportion of both subjects with and without pneumonia in childhood pneumonia etiology studies,[32,91] although this observation typically does not apply to influenza A and B viruses, respiratory syncytial virus, and human metapneumovirus, which are disproportionately associated with case status.

NATs have also been used to detect *S. pyogenes* in throat swab samples, although these methods have not been used widely.[92–94] This situation is likely to change with the recent increased availability of commercial methods[92,94] and the motivation to improve turnaround times to better guide antimicrobial therapy.

Detection of microbial load by quantitative molecular methods has been explored in the effort to help distinguish infection from contamination or colonization. Microorganisms detected in greater quantities may be more likely to be clinically significant. Quantitative multiplex PCR has been used to determine the etiology of community-acquired pneumonia in adults using cutoffs developed for interpretation of culture results from lower respiratory tract specimens.[95,96] Greater confidence in the diagnostic cutoffs will be needed before this approach can be introduced into routine diagnostic use. Quantitative approaches using NATs have also been applied to nasopharyngeal specimens. Among human immunodeficiency virus (HIV)-infected adults in South Africa, quantitative PCR testing of nasopharyngeal samples distinguished between pneumococcal pneumonia and asymptomatic pneumococcal colonization with reasonable diagnostic accuracy.[97,98]

Nasopharyngeal pneumococcal load also distinguished colonization from microbiologically confirmed pneumococcal pneumonia in a large pediatric study, although the diagnostic accuracy was inadequate for clinical use.[99]

NATs have also been applied, with limited success, to nonrespiratory specimens for determining the microbial etiology of respiratory infections in children. There has been particular interest in the testing of blood for *S. pneumoniae* by PCR. Among Italian children, blood PCR detected invasive pneumococcal disease with high specificity.[100–104] However, in other populations positive results have been reported in control participants who do not have suspected pneumococcal disease,[105] with false-positive results being relatively common in children from developing countries where there is a high prevalence of pneumococcal carriage.[106]

The potential application of whole genome sequencing in the diagnostic laboratory is still being realized. This method is already being increasingly used for strain characterization of bacterial isolates as part of epidemiological investigations.[107] However, its precise role in determining the etiology of respiratory infections is uncertain.

## Antimicrobial Susceptibility Testing

Most antimicrobial susceptibility testing methods are performed on pure live bacterial cultures using a variety of standard methods.[108] Several guidelines have been established for interpretation of findings; the most commonly used guidelines are produced by the European Committee on Antimicrobial Susceptibility Testing (EUCAST)[109] and the Clinical and Laboratory Standards Institute (CLSI).[110] These guidelines are comparable, and it is essential that each diagnostic laboratory chooses an approved guideline for interpretation of their antimicrobial susceptibility test results. Increasingly, molecular methods with rapid turnaround times are being used to detect specific antimicrobial resistance mechanisms.[111] This trend is likely to continue given the constant demands for rapid identification of resistant pathogens.

Antiviral susceptibility testing against respiratory pathogens is rarely indicated and has mainly focused on influenza viruses.[112]

# Diagnostic Approach by Syndrome

## Common Cold

Manifestations of the common cold are so typical that diagnostic testing is usually unnecessary. If there is a reason to determine the specific virus involved, testing a nasopharyngeal specimen for respiratory viruses by NAT is the current test of choice.

## Pharyngitis

The main reasons to diagnose the cause of acute pharyngitis are to detect cases caused by *S. pyogenes* and to identify the occasional case due to less common causes, such as *Arcanobacterium haemolyticum* and *Corynebacterium diphtheriae.* Throat swab culture is still the mainstay although antigen detection assays are available. In future, molecular point of care tests are likely to become available to clinicians in primary care.

## Croup

The diagnosis of croup is usually based on the characteristic clinical picture (fever, hoarseness, barking cough, inspiratory stridor, and varying degrees of respiratory distress) and epidemiology. Identification of specific microbial causes can be accomplished by testing a nasopharyngeal specimen for respiratory viruses by NAT.

## Sinusitis

Diagnostic testing is not usually performed on cases of acute sinusitis as the microbial etiology is well described. However, sinus puncture should be performed to obtain specimens for bacterial culture in patients with severe sinusitis, in those who have not responded to empiric antibiotics, and in patients with severe immunosuppression.

## Epiglottitis

*H. influenzae* type b is isolated in cultures of blood and/or epiglottis in most children with epiglottitis. Direct visualization of the epiglottis should be performed in a setting where immediate securing of the airway is possible.

## Bronchiolitis

A specific diagnosis of the causative agent of bronchiolitis can be made by testing a nasopharyngeal specimen for respiratory viruses by NAT.

## Pneumonia

Determining the microbial etiology of pneumonia in children remains challenging, largely due to difficulties obtaining a sample from lungs.[2] Current guidelines for the management of community-acquired pneumonia in children generally recommend that diagnostic tests should mainly be used on patients with severe disease, with a focus on blood cultures and detection of respiratory viruses.[61,113] The development of improved urinary antigen tests and quantitative molecular assays holds hope for the future.

## Pleural Effusion and Empyema

Gram stain and culture of fluid aspirated from the pleural cavity is indicated in patients for whom a diagnosis of infection is considered. The sample can also be tested for pneumococcal antigen by a RADT and nucleic acid detection methods. Testing of pleural fluid increased the yield of *S. pneumoniae* detection by 31% in South African children with empyema.[114]

## Lung Abscess

Needle aspiration provides the best opportunity to identify the microbial cause of an abscess. Abscess fluid may also be recovered by bronchoscopy if it has ruptured. Blood cultures should also be performed in children with suspected lung abscess.

## Infections Associated With Cystic Fibrosis

There is often a close working relationship between clinicians caring for patients with cystic fibrosis and laboratory scientists. Special attention is given by the laboratory to lower respiratory specimens from patients with cystic fibrosis with a particular focus on classic pathogens associated with this disease, such as *Pseudomonas aeruginosa, Burkholderia cepacia* complex, and *S. aureus*.[115] The use of synergy testing to assess antimicrobial combinations is often used in cystic fibrosis patients with multiresistant organisms, although the value of this practice has been questioned.[116]

# Microbiome

Recognition of the possible existence of the lung microbiome has been a major recent revelation in respiratory medicine.[6] Until recently, the lungs in health were regarded as sterile, but the use of modern culture-independent techniques has consistently found evidence of bacteria in the lower airways.[6] Most of these studies have been performed on bronchoscopic specimens, which may be susceptible to contamination, but there is certainly mounting evidence supporting the nonsterility of the lung.

The existence of the lung microbiome has challenged our traditional paradigm of pneumonia pathogenesis, as the traditional view is that pneumonia is caused by a single invasive pathogen in a normally sterile site. There is increasing recognition that bacteria and viruses frequently interact in the causative pathway to pneumonia,[117,118] and the common finding of polymicrobial infection[10] adds further complexity to our understanding of how pneumonia develops. The traditional bacterial versus viral pneumonia concept may be too simplistic. Consequently, we are likely to need more sophisticated approaches to pneumonia diagnosis and interpretation of laboratory results than simply using assays that target single specific putative pathogens.

We have a lot to learn about the lung microbiome and are only just beginning to understand changes in the lung ecosystem during acute infections.[6,119–121] Analysis of the lung microbiome may provide insights into pneumonia etiology and reveal novel markers for pneumonia prognosis and treatment guidance.[122] The following are some examples of recent findings about the respiratory microbiome that may have clinical implications, and they give an indication of the applications that may be available in the future.

Using 16S ribosomal RNA sequencing, a recent study showed that certain taxa in the respiratory microbiota were associated with the clinical course of pediatric pneumonia.[123] In children aged 6 months to 5 years, high relative abundance in sputum of

*Actinomyces, Veillonella, Rothia,* and Lactobacillales was associated with decreased odds of length of stay ≥4 days, and high relative abundance of *Haemophilus* and Pasteurellaceae was associated with increased odds of intensive care unit admission. In children aged 5 to 18 years, high relative abundance in sputum of Porphyromonadaceae, Bacteriodales, Lactobacillales, and *Prevotella* was associated with increased odds of length of stay ≥4 days.

In another recent study, the composition of the nasopharyngeal bacterial community of children was related to the prior history of acute sinusitis.[124] History of acute sinusitis was associated with significant depletion in relative abundance of taxa including *Faecalibacterium prausnitzii* and *Akkermansia* spp. and enrichment of *Moraxella nonliquefaciens.* Children who experienced more frequent upper respiratory infections had significantly diminished nasopharyngeal microbiota diversity.

Other recent data indicate that interactions between RSV and nasopharyngeal microbiota might modulate the host immune response, potentially affecting clinical disease severity,[125] that the nasopharyngeal microbiome at the time of upper respiratory viral infections during infancy may contribute to the ensuing risk for development of asthma,[126] and that the microbiome of children with cystic fibrosis is susceptible to environmental influences, suggesting that interventions to preserve the community structure found in young patients and slow disease progression might be possible.[127]

We can expect to see an exponential increase in publications on the role of the respiratory microbiome in health and disease over the next few years. The extent to which these findings can be readily translated into clinical applications is uncertain.

# Future Prospects

The trend towards increased use of molecular diagnostic tools will probably continue with increased availability of point of care testing. It is also likely that measurement of bacterial and viral pathogen load will be part of those developments, both for distinguishing between colonization and disease and for monitoring response to treatment. Any future developments in diagnostics for respiratory infections must incorporate new knowledge about the lung microbiome. For lower respiratory infections, there is likely to be a move away from the detection of specific known pathogens to measurement of markers of change in the lung microbial ecology during disease. The development of new and better urinary antigen tests would be welcome, as these can be readily adapted to point of care testing.

# Acute Infections That Produce Upper Airway Obstruction

*Ian Michael Balfour-Lynn BSC, MBBS, MD, FRCP, FRCPCH, FRCS(Ed), Marie Wright MBChB, MRCPCH*

Upper airway obstruction due to acute infection is not uncommon in children, and many parents have experienced an anxious night with a "croupy" child. Although infants and young children are most commonly affected because they have relatively narrow upper airways, older children and adults can also have significant symptoms. Fortunately, these are mostly due to self-limiting viral laryngotracheobronchitis (LTB), but there is also a group of bacterial infections (e.g., epiglottitis, bacterial tracheitis, diphtheria, retropharyngeal abscess, and peritonsillar abscess) that can occasionally cause significant obstruction. It is the job of the emergency physician, pediatrician, pediatric pulmonologist, or otorhinolaryngologist to diagnose more serious infections promptly so that treatment can be instituted early and disastrous obstruction avoided. It is also important to recognize when a simple viral LTB is causing significant problems, so that appropriate treatment can be given immediately. This chapter is clinically oriented and outlines the principal infective causes of upper airway obstruction, with an emphasis on diagnosis and treatment. Confusion exists regarding the nomenclature for these disorders, with some using the term *croup* to refer to any inflammatory disorder of the upper airway, whereas others restrict its use to subglottic disease (i.e., LTB, which is usually of viral origin). Therefore, for the sake of clarity, the term *croup* will be largely avoided in this chapter.

The consequence of these upper airway infections is usually stridor, which is a clinical sign and should not be considered a definitive diagnosis. This section briefly outlines the principles behind what causes stridor, which should clarify why this condition mostly affects infants and young children. The appendix in Holinger and colleagues' *Pediatric Laryngology and Bronchoesophagology* discusses the physics of air flow and fluid dynamics.[1] The laws of fluid dynamics are based on flow through fixed tubes and may not always apply to dynamic airways in vivo. Normally, air flow through the upper airways is laminar, and the moving column of air produces slight negative pressure on the airway walls.[2] Inflammation resulting from infection causes a degree of airway narrowing, which increases the flow rate through the narrowed segment (the Venturi effect). This, in turn, causes a reduction in the pressure exerted on the airway wall. This is the Bernoulli principle. In other words, negative intraluminal pressure increases. This enhances the tendency of the airway to collapse inward, further narrowing the airway and causing turbulent air flow. The respiratory phase (inspiration or expiration) has a differential effect on air flow, depending on whether the obstruction is intrathoracic or extrathoracic (Fig. 23.1). Stridor is the sound made by rapid, turbulent flow of air through a narrowed segment of a large airway. It is most often loud, with medium or low pitch, and inspiratory. It usually originates from the larynx, upper trachea, or hypopharynx.[3] Progression of the disease process may make stridor softer, higher-pitched, and biphasic (inspiratory and expiratory). With the onset of complete obstruction, stridor may become barely audible as minimal air moves through the critically narrowed airway.[4]

**FIG. 23.1** The effect of the respiratory phase on extrathoracic and intrathoracic obstruction is shown. During inspiration, negative intratracheal pressure (relative to atmospheric pressure) leads to dynamic collapse of the extrathoracic airway, thus worsening the effects of an extrathoracic obstructive lesion. In contrast, intrathoracic obstruction improves during inspiration because the elastic recoil of the lung parenchyma opens the intrathoracic airways. During expiration, intratracheal pressure is positive relative to atmospheric pressure, opening the extrathoracic trachea and lessening the obstructive effect of lesions. In contrast, intrathoracic obstruction worsens because of lower pressure in the airways relative to the surrounding parenchyma, collapsing the airways. (From

Loughlin GM, Taussig LM. Upper airway obstruction. *Semin Respir Med.* 1979;1:131-146.)

The laryngeal anatomy of children makes them particularly susceptible to narrowing of the upper airways. The larynx of a neonate is situated high in the neck, and the epiglottis is narrow, omega-shaped (ω), and vertically positioned.[5] The narrowest segment of the pediatric airway is the subglottic region (in adults, it is at the glottic level), which is encircled by the rigid cricoid cartilage ring. There is nonfibrous, loosely attached mucosa in this region that is easily obstructed in the presence of subglottic edema. In addition, the cartilaginous support of the infant airway is soft and compliant, easily allowing dynamic collapse of the airways during inspiration. Young children have proportionally large heads and relatively lax neck support; this combination increases the likelihood of airway obstruction when supine.[6] Also, their tongues are relatively large for the size of the oropharynx. Simple mathematics shows why a small amount of edema has such a profound effect on the cross-sectional area and hence air flow. The diameter of the subglottis in a normal newborn is approximately 5 mm, and 0.5-mm edema in this region reduces the cross-sectional area to 64% of normal (area = π ∞ radius[2]). Air flow is directly proportional to the airway radius to the fourth power (Poiseuille's law), so a small reduction in caliber has a major effect on flow rate. The same 5-mm airway with 0.5 mm edema will have a flow rate of only 41% of baseline, assuming that pressure remains unchanged—a situation that is not necessarily the case if the Bernoulli principle is in play. Because the caliber of the airway is almost inevitably reduced further in accord with the Bernoulli principle, and Poiseuille flow is not established, the flow rate is much further reduced, and the work of breathing is greatly increased to maintain ventilation.

# Viral Laryngotracheobronchitis

## Epidemiology

Viral LTB is the most common cause of infective upper airway obstruction in the pediatric age group. Affected children are usually of preschool age, with a peak incidence between 18 and 24 months of age.[7] Although viral LTB episodes become uncommon beyond 6 years of age, cases have been reported during later childhood and adolescence, and rarely described in adults. Reported annual incidence rates in preschool children vary from 1.5% to 6%, but less than 5% of these require hospital admission, and only 1% to 2% of those admitted require endotracheal intubation and intensive care.[8] This proportion has fallen dramatically since the use of corticosteroids has become routine. Mortality is low, reported by one 10-year follow-up study as less than 0.5% of intubated patients.[9] There is a male preponderance in children younger than 6 years of age (1.4 : 1), although both sexes appear to be affected equally at an older age.

Children with a specific CD14 genetic polymorphism (C/C variant of CD14 C-159T) have recently been described as having a reduced prevalence of croup. It has been hypothesized that this relates to the role of the CD14 gene as a pattern recognition receptor in the mediation of the innate immune system response to LTB-causing viruses.[10]

Cases may occur in epidemics, with those caused by parainfluenza virus (PIV) type 1 typically presenting in fall and winter months. Infections caused by other common organisms, including other PIV subtypes, occur more commonly as isolated infections. Infection is via droplet spread or direct inoculation from the hands. Viruses can survive for long periods on dry surfaces, such as clothes and toys, emphasizing the importance of infection-control practices.

## Etiology

The most common etiologic agents are the PIVs, of which PIV 1 is found most frequently and leads to epidemics. PIV 2 may account for many sporadic cases, and PIV 3 is a less common cause of viral LTB, usually targeting the epithelium of the smaller airways and leading to bronchiolitic illness. Less is known about the clinical presentation of PIV 4, but it is reported to result in milder clinical illness and is infrequently associated with croup symptoms.[11] The PIVs belong to the *Paramyxoviridae* family, along with respiratory syncytial virus, measles, mumps, and the recently identified human metapneumovirus.[12] Together the PIVs account for more than 75% of viral LTB cases, although other respiratory viruses (e.g., respiratory syncytial virus, rhinovirus, adenovirus, coronavirus, human bocavirus, and enteroviruses) can produce a similar clinical syndrome. Herpes viruses and influenza viruses tend to cause a more severe and protracted form of the disease.[13] LTB can also occur with some systemic infections, such as measles and, less commonly, mycoplasma. In general, however, it is not usually possible to identify the cause of infection from the child's symptoms because severity does not correlate with any particular etiologic agent.

## Pathology

Infection affects the larynx, trachea, and bronchi, although swelling and inflammation in the subglottic area leads to the characteristic clinical features of viral LTB. In addition to relative differences in airway size (discussed earlier in the chapter), it is suggested that poor cell-mediated immunity in younger age groups also accounts for differences observed between adults and children.[14] The epithelium of the subglottis possesses abundant mucous glands, secretions from which can further narrow the airway lumen in response to infection. The PIVs are trophic for the respiratory epithelium, binding in particular to ciliated cells via an interaction between the viral hemagglutinin-neuraminidase protein and its receptor, sialic acid. Other viral proteins (the F protein in particular) are important in membrane fusion and the passage of viral particles between cells. Many strains of PIV are cytopathic, with infection leading to the formation of giant cells and cell death. As with many infective processes, the ensuing inflammatory response is involved in the evolution of symptoms. Both polymorphonuclear and monocytic leukocytes infiltrate the subepithelium, which leads to vascular congestion and airway wall edema. In addition, the symptoms of viral LTB are believed to be caused by the release of spasmogenic mediators, leading to decreased airway diameter. This may result from a type I hypersensitivity response to PIV, and some authors have postulated a role for anti-PIV-specific immunoglobulin E (IgE) in the development of airway narrowing.[15] These factors may play a relatively greater role in patients with recurrent (spasmodic) croup, and these patients may have hyperreactivity of the extrathoracic and intrathoracic airways.[16]

The etiology of recurrent, spasmodic croup remains unclear, with authors expressing differing views on whether it is usually virus-related[17] or is a separate disease entity; suggested triggers include gastroesophageal reflux, eosinophilic esophagitis,[18] and anatomical abnormalities, in addition to an allergic predisposition.[19]

## Clinical Features

### Mild

Most children are affected mildly by viruses that cause LTB.[7] The exact incidence remains unknown, because many of them do not receive medical attention, but are managed by parents at home. Children have a barking cough and a hoarse cry or voice; these symptoms are worse in the evening and at night. They may also have inspiratory stridor on exertion, but stridor at rest is usually absent, as are other signs of respiratory distress. There is most commonly a coryzal prodrome accompanied by a low-grade fever, but children are not particularly unwell or toxic. They remain interested in their surroundings, are playful, and still eat and drink.

### Moderate

Features of moderate viral LTB include those discussed earlier, but with inspiratory stridor present at rest, as well as a degree of respiratory distress manifest by chest wall recession, tachypnea, and the use of accessory muscles of respiration. There is usually accompanying tachycardia, but children remain interactive and are able to take at least liquids orally.

### Severe

Progression from moderate to severe infection can occur rapidly and may be precipitated by the distress caused by clinical examination. Worrisome signs include those of increasing respiratory distress, with the child appearing anxious or preoccupied and tired. Drooling may occur (but not as commonly as in epiglottitis), and the child will often refuse liquids or be unable to coordinate swallowing and breathing. However, the child with viral LTB will not appear toxic, with high fever and flushed face, as do those with the classic signs of bacterial epiglottitis (Table 23.1). Another difference is in the nature of the cough; a harsh, barking cough is not commonly associated with epiglottitis (in which there is often a muffled cough and cry). Restlessness and agitation are late signs of airway obstruction of any cause, as is cyanosis, pallor, or decreased level of consciousness. Pulse oximetry should be performed, but limitations must be recognized. Oxygen saturation may be well preserved until the late stages of severe viral LTB, and it can lead to significant underestimation of respiratory compromise in a patient who is receiving supplementary oxygen. Conversely, desaturation may be seen in children with relatively mild airway obstruction (presumably reflecting lower airway involvement and ventilation-perfusion mismatch).[20] Pulsus paradoxus is present in the group with severe disease, but in clinical practice, it is difficult to assess, and attempts to do so could worsen symptoms by causing distress.

## Table 23.1

## Differentiation of Principal Infective Causes of Upper Airway Obstruction

| | **Viral Laryngotracheobronchitis** | **Epiglottitis** | **Bacterial Tracheitis** | **Diphtheria** |
|---|---|---|---|---|
| Principal organisms | Parainfluenza 1–3<br>Adenovirus respiratory syncytial virus | *Haemophilus influenzae, Streptococcus* | *Staphylococcus aureus, Moraxella catarrhalis, H. influenzae* | Corynebacteriu diphtheria |
| Age range | 6 months–4 years (peak, 1–2 years) | 2–7 years | 6 months–8 years | All ages |
| Incidence | Common | Rare | Rare | Rare if vaccinat |
| Onset | Insidious usually follows upper respiratory tract infection | Rapid | Slow, with sudden deterioration | Insidious |
| Site | Below the vocal cords | Supraglottis | Trachea | Tonsils, pharyn larynx, nose, sk |
| Clinical manifestations | Low-grade fever<br>Nontoxic barking (seallike) cough<br>Stridor hoarseness | High fever<br>Severe sore throat<br>Minimal | High fever<br>Toxic, brassy cough | Fever<br>Toxic strido<br>Sore throat<br>Fetor oris |

| | | | | |
|---|---|---|---|---|
| | Restlessness | nonbarking cough<br>Toxic stridor<br>Drooling<br>Dysphagia<br>Muffled voice<br>Tripod position | Stridor<br>Hoarse voice<br>Neck pain<br>Choking | Cervical lymphaden<br>Bull neck |
| Endoscopic findings | Deep red mucosa<br>Subglottic edema | Cherry-red or pale and edematous epiglottis<br>Edematous aryepiglottic folds | Deep red mucosa<br>Ulcerations<br>Copious, thick tracheal secretions<br>Subglottic edema, with normal epiglottis and arytenoids | Gray, adherent membrane on t pharynx |
| Intubation | Occasional | Usual | Usual | Occasional |
| Therapy | Corticosteroids<br>Nebulized epinephrine | Intubation (1–3 days)<br>IV antibiotics | Intubation (3–7 days)<br>IV antibiotics<br>Tracheal suction | Diphtheria antitoxin<br>IV antibioti<br>Immunizati during convalescen |

*IV*, Intravenous.

## Diagnosis and Differential Diagnosis

The diagnosis of croup is made clinically, based on the features described earlier; there is no role for laboratory tests or radiography in the assessment of acute airways obstruction. In skilled hands, plain lateral neck radiographs may demonstrate sites of obstruction, but this rarely influences management; it also wastes time and can be dangerous. The neck extension that is required could precipitate sudden worsening of airway obstruction, which can be fatal in severe cases. Investigations during the acute illness should be reserved for children with an atypical presentation or who fail to respond to conventional treatment. In such cases, alternative infective (e.g., epiglottitis) and noninfective (e.g., inhaled foreign body) causes of acute airway obstruction require careful exclusion (see Box 23.1 and Table 23.1). Advice from a senior clinician is vital when croup is severe.

**Box 23.1**

### Infectious and Noninfectious Causes of Acute Upper Airway Obstruction

#### Infectious

Viral laryngotracheobronchitis
Epiglottitis
Bacterial tracheitis
Diphtheria
Retropharyngeal abscess
Peritonsillar abscess
Infectious mononucleosis

#### Noninfectious

Foreign body
Trauma
Caustic burns
Spasmodic croup
Angioneurotic edema
Hypocalcemia (e.g., hypoparathyroidism)

## Recurrent or Spasmodic Croup

Symptoms are similar to those of the more typical forms of viral LTB, but children are often older, do not have the same coryzal prodrome, and may be afebrile during the episode. There may be links with atopy, often with a positive family history. Episodes are often similar to acute asthma except the child has stridor rather than wheeze. Attacks often occur suddenly, at night, and may resolve equally quickly. Treatment must be guided by the degree of severity, and is similar to that for viral LTB. Some practitioners prescribe oral or inhaled corticosteroids (via a nebulizer) to be kept at home and administered by the parents in case of an episode, although there is a paucity of evidence for or against this practice in spasmodic croup.

## Noninfective Causes of Acute Airway Obstruction

There are a number of noninfective causes of upper airway obstruction, and these must be considered in the differential diagnosis of infective causes (see Box 23.1). Foreign body inhalation is the most common noninfective cause in children. Symptoms may partly mimic those of viral LTB and will depend on the location of the foreign body, the degree of resultant airway obstruction, and (to a lesser extent) the nature of the foreign body. Onset of symptoms may be either acute or insidious; a large foreign body may cause severe obstruction, whereas a smaller one may simply lead to laryngeal and tracheal irritation and airway edema. In cases of severe airway obstruction, the voice may be lost and breath sounds quiet. This condition is an emergency, and requires immediate visualization of the larynx and trachea and removal of the foreign body by a physician or surgeon experienced in this procedure. Occasionally an unrecognized inhaled foreign body leads to chronic stridor. Acute upper airway obstruction may also result from the ingestion of caustic substances, with resulting pharyngeal burns, edema, and inflammation of the epiglottis, aryepiglottic folds, larynx, and trachea. This diagnosis is usually clear from the history. Rarely, angioneurotic edema may cause acute laryngeal swelling and airway obstruction. Patients appear nontoxic and may exhibit other signs of allergic disease, such as urticaria and abdominal pain. In hereditary angioneurotic edema due to C1 esterase inhibitor deficiency, the family history may be positive, although the first presentation is more common in adults than in children. Hypocalcemia, for example, due to hypoparathyroidism, can lead to laryngospasm (a form of tetany), which can cause stridor with significant airway obstruction.[21]

There are numerous causes of chronic airway obstruction that are discussed elsewhere in this book. Confusion may arise when an upper respiratory tract infection unmasks a previously asymptomatic congenital abnormality. For example, mild subglottic stenosis may cause symptoms only with the additional burden of airway edema due to a simple viral upper respiratory infection. It is important to ensure that there is no history of intubation (which may have been brief, as in resuscitation of a newborn in the maternity unit) or of any coexisting signs (e.g., a cutaneous hemangioma) that may increase the index of suspicion for a congenital airway abnormality. One catch with subglottic hemangiomata is that they may initially respond to systemic steroids, and thus their diagnosis may be masked with the assumption that stridor was due to viral croup.[22]

## Management of Viral Laryngotracheobronchitis

Management of viral LTB must be based on clinical assessment of severity. Several scoring systems have been devised,[23] and the most commonly applied system (the 17-point Westley scale, which assesses degree of stridor, chest retractions, air entry, cyanosis, and level of consciousness) has been well validated. However, these are mainly used in the context of clinical trials and are not a substitute for experienced clinical assessment.

### Supportive Care

Children with mild croup can be managed at home. They should be treated with plenty of fluids and antipyretics as required. Because the vast majority of cases are of viral etiology, there is no role for the routine use of antibiotics in the absence of other features suggestive of bacterial infection. Parents should be warned that symptoms are usually worse at night and may recur after apparently disappearing during the day.

### Humidification

Both at home and in the hospital setting, humidified air (either steam or cool mist) has been used for more than a century to produce symptomatic relief from croup. Despite this, there is very little supportive evidence; most early studies, some of which may have been underpowered, generally suggested no benefit.[24–26] A larger study of 140 moderately affected children showed no differences in signs or requirement for additional treatments with optimally delivered 100% humidity,[27] and the most recent Cochrane Systematic Review has also concluded there is no evidence of benefit.[28] Case reports have described severe burns caused by spilling of boiling water and facial scalds from the use of steam, so this type of treatment is not without the potential for harm.[29]

## Corticosteroids

The use of corticosteroids has received much attention for more than a decade, and their therapeutic role is well established. Their mechanism of action, however, remains unclear, although is believed to relate to rapid-onset antiinflammatory properties. The cumulative evidence strongly supports their use in children with moderate to severe symptoms, although there are still outstanding questions, including the optimal route of administration, the most appropriate dosing regimen, and the best oral agent.

The role of corticosteroids in the management of croup in children has been the subject of several Cochrane reviews, with the most recent update in January 2011.[30] In this review, the authors identified 38 studies that fulfilled their criteria for inclusion—namely, randomized controlled trials in children measuring the effectiveness of corticosteroids (any route of administration) against either a placebo or another treatment. A total of 4299 children were included, the majority from double-blind, placebo-controlled trials. Outcome measures included the croup score (most commonly the Westley scale), the requirement for admission or return visit, the length of stay, the requirement for additional therapeutic interventions, and overall assessment of “improvement” (indicated by a minimum incremental improvement in croup score or subjective relief of symptoms). Overall, treatment led to an improvement in the croup score at 6 and 12 hours, with a number needed to treat (NNT) of 5 calculated in order to achieve clinical improvement in one child at both those time points. The improvement was no longer apparent at 24 hours, but this was thought to be a reflection of reduced statistical power due to the small number of participants evaluated at 24 hours. The length of time spent in either the emergency department or the hospital was also significantly decreased, as was the requirement for nebulized epinephrine. Importantly, and in contrast to the first version of this Cochrane review, the authors concluded with funnel plots and other statistical methods that these results were not influenced by publication bias. In conclusion, there is convincing evidence that corticosteroids provide effective and sustained treatment of croup symptoms, leading to clinical improvement within 6 hours of administration. In severe disease, rates of intubation are significantly decreased and the duration of intubation is reduced, and in moderate disease admission, the need for additional treatment and return visits are reduced.[8] More recent studies have focused attention on the optimal formulation, dose, and treatment regimen.

## Optimal Route of Administration, Formulation, and Dosing Regimen

Studies included in the Cochrane review (discussed earlier in the chapter) and others conducted since then have used the intramuscular, oral, or nebulized route to administer different corticosteroid preparations. This area has been well reviewed recently.[8] From the studies that have attempted to address the route of administration, nebulized, oral, and intramuscular routes appear, in general, to be roughly equivalent. Nebulization could potentially increase distress of the child and worsen upper airway obstruction, although it may be preferable in a child who is vomiting or having difficulty swallowing.

Similarly, studies using oral agents have used either dexamethasone or prednisolone, and both in varying doses. Many primary care physicians who visit homes do not routinely carry dexamethasone but do carry oral prednisolone. There is no strong evidence in support of one preparation over the other, although one recent study favored dexamethasone, which led to a reduced frequency of re-presentation.[31] In contrast, a recent Australian trial compared 1 mg/kg prednisolone with a single dose of oral dexamethasone using two different dosing regimens (0.15 and 0.6 mg/kg) and found no difference in croup score, requirement for further treatment, or re-presentation.[32] Similarly, a community-based double-blind trial comparing a single dose of dexamethasone 0.6 mg/kg with three doses of 2 mg/kg prednisolone on consecutive days found no difference in additional health care attendances, duration of symptoms, parental stress, or sleep disturbance.[33] With regard to dexamethasone, 0.6 mg/kg has been the dose most widely used, but several studies have demonstrated that this dose may be higher than required and that 0.15 mg/kg is just as effective.[32,34–36] A practical approach might be to use dexamethasone, if available, at a dose of 0.15 mg/kg. If this preparation were not available at a home visit, prednisolone (at an equivalent dose of 1 mg/kg) could provide a useful substitute. Due to the short duration of symptoms in a typically episode of croup, one dose of steroid is usually sufficient treatment. However, a second dose should be considered if residual symptoms are still present the following day, and can be given to the parents to administer at their discretion.

### Nebulized Epinephrine (Adrenaline).

The most recent update of the Cochrane Review of nebulized epinephrine use in croup was published in 2013.[37] It included eight randomized controlled studies, with a total of 225 subjects comparing the efficacy of nebulized epinephrine to placebo (six studies), or comparing different epinephrine formulations and delivery methods (two studies).

All studies involved the management of moderate to severe croup in either an emergency department or hospital setting. Outcome measures used were croup score, intubation rates, side effect profile, and total health care utilization. Nebulized epinephrine was associated with improved clinical severity score 30 minutes posttreatment, but this effect was not sustained at 2 or 6 hours posttreatment. Magnitude of benefit was consistent between studies, and similar, irrespective of whether epinephrine was administered in an inpatient or outpatient setting.

Duration of hospitalization was also significantly reduced with epinephrine (mean difference of 32 hours), although this outcome was only assessed in one study. No studies provided a comparison of intubation rate or side effect profile. In summary, nebulized epinephrine has been shown to improve clinical severity in the short term and reduce hospital admission in cases of moderate to severe croup. It should be used in any child who has severe signs and symptoms, and it should be considered for those with moderate signs and symptoms, depending on the signs of respiratory distress and possible response to corticosteroid administration. It can be administered in the home setting while awaiting an ambulance, but clearly any child requiring this treatment at home must be transferred promptly to the hospital for monitoring. Multiple doses may be administered, although the requirement for this must lead to consideration of the need for intensive care management. Although rebound worsening of symptoms after administration of nebulized epinephrine is often alluded to, in practice, this phenomenon does not appear to be a real risk. Traditionally, children treated with epinephrine have been admitted to the hospital, but recent studies have confirmed that discharge home is safe after 3 to 4 hours of observation if the child has made significant improvement.[38]

Most clinical trials have used the racemic form of this drug,[39] although there is evidence that the L-isomer used alone (which is the only available formulation in some units) may be equally effective and has a longer duration of action.[40] The mechanisms of action are believed to be a combination of rapid reduction in airway wall edema and bronchodilation. The recommended dose is 0.4 to 0.5 mL/kg (to a maximum of 5 mL) of the 1 : 1000 preparation that is put undiluted into the nebulizer cup. Intramuscular epinephrine is not used in severe stridor, so it is important to ensure the stridor is not due to acute anaphylaxis, in which case it should be given.

### Other Treatments for Severe Cases.

Oxygen should be administered to any child with severe airway obstruction, even in the absence of severe hypoxia, because it will aid respiratory muscle function. As mentioned earlier, a child with severe respiratory distress and obstruction may have normal pulse oximetry readings when breathing oxygen, which can be dangerous if misinterpreted by staff who are unaware of this limitation. Heliox (70% to 80% helium with 20% to 30% oxygen) has been used in both upper airway obstruction[41] and severe asthma, and it is the focus of a recent Cochrane review.[42]

Three randomized controlled trials were identified totaling 91 participants with croup of varying severity. Heliox was compared with either 30% humidified oxygen, 100% oxygen plus epinephrine, or against no treatment. No pooled analysis was possible, as each study used a different comparator. Collectively, these studies provided evidence of a short-term benefit of Heliox inhalation, with improved croup scores at 60 to 90 minutes following administration. However, this clinical improvement was not sustained over subsequent hours. The authors summarized that no additional benefit appeared to have been provided by Heliox beyond that delivered by administration of 30% oxygen in cases of mild croup, or 100% oxygen plus nebulized epinephrine in moderate to severe croup. Adequately powered studies are required to further evaluate the role of Heliox in the management of moderate to severe croup.

## Endotracheal Intubation

Some children with severe croup either do not respond to the usual therapies or are too severely compromised at presentation to permit their use. These children require urgent endotracheal intubation and mechanical ventilation to avoid potentially catastrophic complete airway obstruction and the serious sequelae of hypoxia and hypercapnia (e.g., hypoxic ischemic encephalopathy). Intubation should be performed by the most experienced person available, and it should be attempted with an uncuffed endotracheal tube one size smaller than the usual size for the child.[43] Facilities for immediate tracheostomy must be available at the time of intubation. Children may have coexisting lower airway and parenchymal involvement that impairs gas exchange and may lead to slower than expected clinical improvement after intubation. Rarely, pulmonary edema may develop after relief of airway obstruction, particularly if the disease course has been prolonged. Most children without severe parenchymal involvement require respiratory support for 3 to 5 days.[43] This is one context in which multiple rather than single doses of corticosteroids are often administered. The timing of extubation will depend on the development of an air leak around the endotracheal tube, indicating resolution of airway narrowing.[43] Reintubation rates of approximately 10% have been reported.[44]

## Prevention

Because of the substantial health care costs associated with management of PIV infections (estimated annual costs of $43, $58, and $158 million for hospitalizations in the United States for PIV-associated bronchiolitis, croup, and pneumonia, respectively), there is much interest in development of an effective PIV vaccine.[45] The most promising candidate vaccine developed to date is an intranasally administered cold-adapted PIV 3 vaccine that appears to be well-tolerated and immunogenic in infants as young as 1 month of age.[46] Also under evaluation is a PIV3-vectored RSV vaccine that would confer protection against both of these common respiratory viruses. Results from efficacy studies into each of these promising vaccine candidates are awaited.

## Prognosis and Further Evaluation

Most children with viral LTB were previously well, have short, self-limiting symptoms, and make a full recovery. The lack of complete immunity and the variety of agents that can cause viral LTB mean that more than one episode is not uncommon, particularly in separate seasons.

Recurrent (≥3) episodes have been reported in more than 60% of affected children, with family history of croup identified as the most significant risk factor for recurrence in one case-control study.[47] Although further evaluation is not necessary in every case of recurrent croup, it should be considered in cases that are particularly severe or frequent, if symptoms are particularly slow to resolve, or if symptoms occur between or in the absence of obvious infections. Evaluation of patients in this group is aimed at identifying an underlying airway abnormality that would predispose the child to more severe airway narrowing with viral infections, or that could cause problems independently of such infection. Investigation is usually centered on airway endoscopy. This must be performed in a unit and by an operator who is experienced in the technique because there is a risk of exacerbating the airway obstruction. Spontaneous breathing is necessary to identify vocal cord problems or airway malacia, and anesthetic techniques must be carefully considered. If an inhaled foreign body is considered likely, rigid bronchoscopy is the study of choice. Additional studies that might be considered once the acute episode has resolved include plain lateral neck and chest radiographs, computed tomography or magnetic resonance imaging, contrast assessment of the upper airway (e.g., videofluoroscopy, barium swallow), and a pH probe study. Polysomnography may help determine the severity of chronic symptoms. Rarer causes of recurrent stridor (e.g., hypocalcaemia or angioneurotic edema) are diagnosed by blood testing.

# Epiglottitis

## Epidemiology

*Haemophilus influenzae* type B (HiB) vaccines were first licensed in the United States in 1988, with widespread immunization programs in place by the early 1990s. Since then, reported cases of invasive HiB disease (including epiglottitis) in children younger than 5 years of age have declined by 99%.[48]

By 2008, the overall incidence in the United States had fallen to 1.55 per 100,000, having been 4.39 per 100,000 in 1989.[49] The same pattern has been repeated in Europe, with significant reductions in the United Kingdom.[50,51] Immunization was introduced in the United Kingdom in 1992, and with immunization coverage exceeding 90%, the decline in incidence was more than 95%.[51] In 1998, the incidence in those younger than 5 years of age was 0.6 per 100,000, compared with 31 to 36 per 100,000 in England and Wales before the introduction of the vaccine.[51] However, in 2003 there was a resurgence of HiB infections in the United Kingdom, which led to the launch of a booster program. By 2012, in England and Wales, the incidence had fallen further to 0.06 per 100,000 aged less than 5 years (0.02 per 100,000 for all ages).[49] Ethnicity plays a part in vaccine efficacy. Data from 1996 to 1997 in the United States show that the average annual incidence of HiB invasive disease per 100,000 children younger than 5 years of age was 0.5 among non-Hispanic whites, 0.6 among Asians and Pacific Islanders, 0.7 among non-Hispanic blacks, 0.7 among Hispanic Americans, and 12.4 among Native Americans and Alaskan natives.[48] Nevertheless, cases of epiglottitis due to HiB continue to be reported,[52] as do cases due to other organisms.[53]

Cases of invasive HiB occur principally in nonimmunized children, but also rarely in some true vaccine failures. Clinical risk factors for vaccine failure include prematurity, Down syndrome, malignancy, developmental delay, and congenital or acquired immunodeficiency, principally with reduced immunoglobulin concentrations ($IgG_2$ subclass, IgA, IgM) or neutropenia.[54] However, these factors explain fewer than 50% of cases of vaccine failures.[54] An HiB IgG antibody titer of ≥0.15 μg/mL confers protection from disease, but given the natural waning in antibody levels, it is estimated that a titer of ≥1.0 μg/mL should provide long-term protection.[52] However, sometimes there are qualitative functional problems with antibody responses that are not yet fully elucidated.

Among the pediatric cohort, epiglottitis tends to occur in children 2 to 7 years of age, but cases have been reported in those younger than 1 year of age.[2] Since the introduction of HiB vaccine, the peak age distribution has increased slightly.[55] A review of a national US dataset from 1998 to 2006 has shown that the mean age of a patient admitted with epiglottitis is 45 years, and the national mortality rate is 0.89%; there is a decrease in admissions for those under 18 years of age (with greatest risk at <1 year) and an increase in the 46- to 64-year-old group.[56] This is similar in England and Wales, where 68% of culture-positive cases of epiglottitis occurred in patients aged 45 or over.[49] Most cases occur in the fall and winter.

## Etiology

Historically, HiB was responsible for almost all (approximately 99%) cases of epiglottitis in otherwise healthy children. Since the introduction of HiB immunization, other organisms have been implicated, including groups A, B, C, and G β-hemolytic *Streptococcus.* Other responsible organisms include *H. parainfluenzae, Staphylococcus aureus, Moraxella catarrhalis, Streptococcus pneumoniae, Klebsiella, Pseudomonas,* Candida, and viruses (e.g., herpes simplex, varicella, PIV, influenza, and Epstein-Barr virus).[2,53,57]

## Pathology

Although HiB has a low point-prevalence of nasopharyngeal carriage (1% to 5%), most young children become colonized with HiB in the first 2 to 5 years.[58] The relationship between asymptomatic carriage, immunity, and the development of invasive disease is not clearly understood. Viral coinfection may have a role in the transition from colonization to invasion.[59] Colonies of HiB organisms reside in the nasal mucosal epithelium and submucosa. Invasive disease occurs when organisms disseminate from the mucosa of the upper respiratory tract via the bloodstream; bacteremia increases over a period of hours, and metastatic seeding can occur.[58] Thus, although situated in close proximity to the nose, the supraglottic area is likely to be affected via the bloodstream; direct spread along mucosal surfaces may also play a part. This may account for the relatively high yield of positive blood cultures in epiglottitis and the relatively low incidence of epiglottitis among carriers of HiB.

Epiglottitis is more correctly called *supraglottitis.* It is a bacterial cellulitis of the supraglottic structures, particularly the lingual surface of the epiglottis and the aryepiglottic folds.[2] Destruction of the infected epithelial tissue results in mucosal ulcerations, which may appear on the epiglottis, larynx, and trachea. The submucosal glands are involved as well, with the formation of epiglottic abscesses. Infection of the epiglottis itself causes a local inflammatory response that results in a cherry-red edematous epiglottis when caused by HiB (Fig. 23.2), although it tends to be pale and edematous and accompanied by edematous aryepiglottic folds when caused by *Streptococcus.*[48,53] As supraglottic edema worsens, the epiglottis is displaced posteriorly, and it may obstruct the airway.

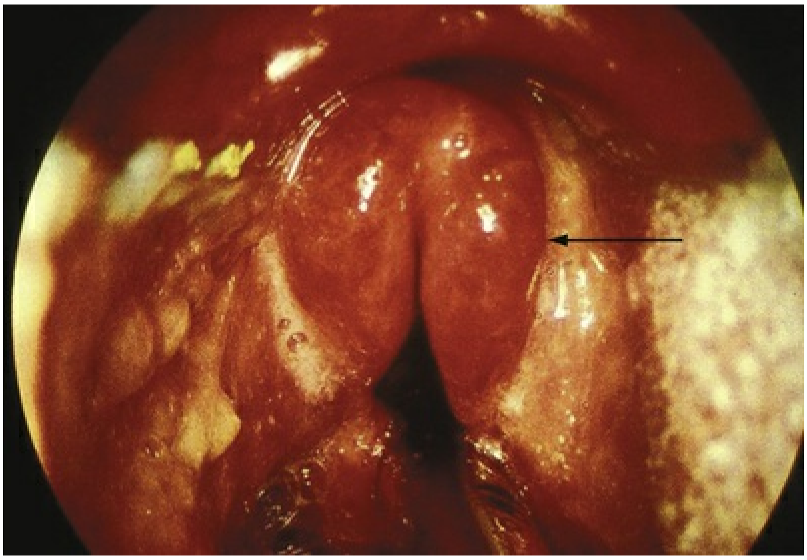

**FIG. 23.2** Swollen epiglottis *(arrow)* caused by acute epiglottitis in an intubated child. (From Benjamin B, Bingham B, Hawke M, et al. *A Colour Atlas of Otorhinolaryngology.* London: Taylor & Francis; 1995:292, with permission.)

## Clinical Features

Classic epiglottitis caused by HiB is a fulminant disease in an otherwise healthy child, who can be near death in a few hours. It is a medical emergency that can be alarming for the medical staff and devastating for the family. Epiglottitis clearly has not been eliminated, but due to its rarity there are concerns about a potential lack of familiarity with its management among emergency physicians, pediatricians, anesthesiologists, and otolaryngologists.[60] Up to 20% of infants with epiglottitis are misdiagnosed initially, usually with viral LTB.[4] Typically there is a short history of fever, severe throat pain, stridor, and respiratory distress, but the symptoms progress rapidly. Children become toxic and tend to sit anxiously in the classic tripod position (sitting upright, with the chin up, mouth open, bracing themselves on their hands) as air hunger develops (Fig. 23.3). They often drool because they cannot swallow their secretions, and the voice is muffled due to pain and soft tissue swelling. Stridor may progress, and when marked (or if it disappears completely), signals almost complete obstruction of the airways. Complete, fatal airway obstruction may occur suddenly and without warning. The most serious complication of this disease process (and any infective upper airway obstruction) is hypoxic ischemic encephalopathy resulting from respiratory arrest. This tragic complication is almost always preventable with clinical suspicion, prompt diagnosis, and correct management. However, a 13-year case series demonstrated that cardiac arrest occurred in 3 of 40 cases (7.5%), although there were no long-term sequelae.[52] Secondary sites of HiB infection may be present in approximately half of cases, and include meningitis, otitis media, pneumonia, and cellulitis; descending necrotizing mediastinitis has been reported. Therefore repeated physical examination during the admission is critical.[2] The pneumonia may contribute to poor gas exchange.

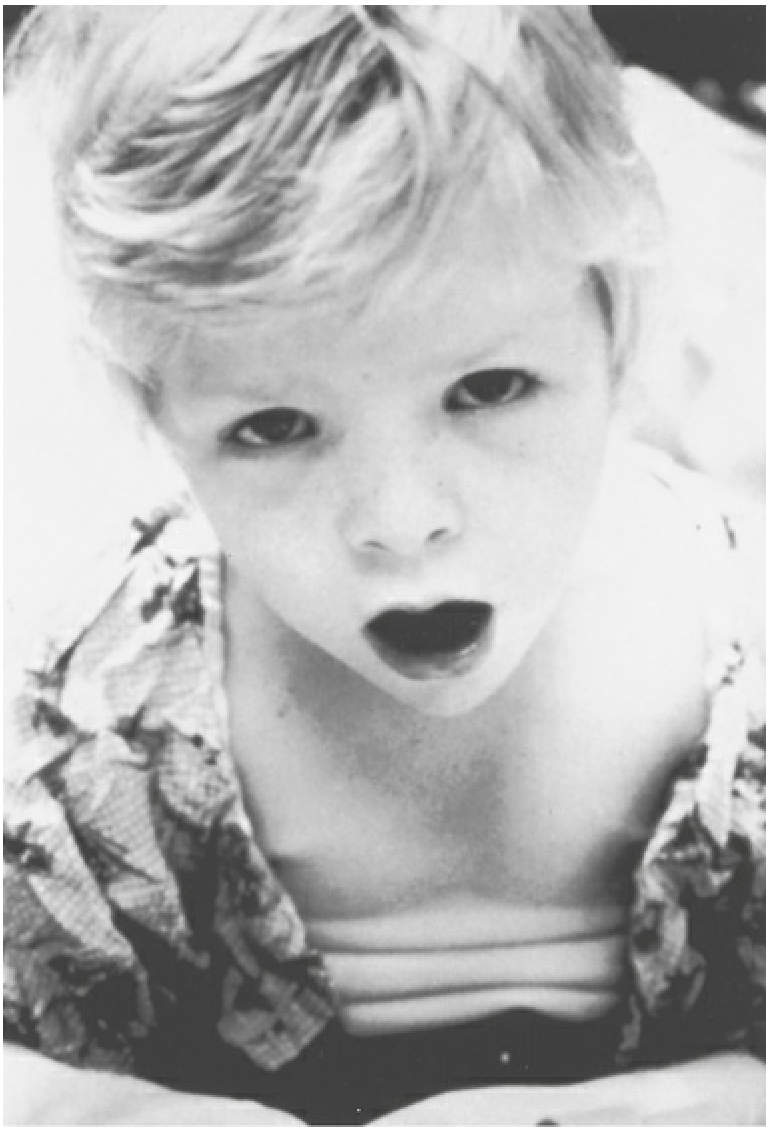

**FIG. 23.3** Characteristic posture in a patient with epiglottitis. The child is leaning forward and drooling,

with a hyperextended neck. (Courtesy of Dr. Robert Berg.)

In general, distinction from standard viral LTB is based on the older age of the child, the lack of history of upper respiratory tract infection, the speed of progression, the degree of toxicity, the extent of drooling, the use of the tripod position, and minimal cough (see Table 23.1). However, it is important to remember that most of these symptoms can be present in acute severe upper airway obstruction from other causes.

The presentation and clinical course of epiglottitis caused by the various types of β-hemolytic streptococcal pathogens are similar to each other, but they differ from those associated with HiB.[53] The onset of disease is more gradual, but the resolution of tissue damage and the time to recovery are longer, with a mean intubation time of 6 days.[53,61]

## Management

The first priority and key response to the diagnosis must be to secure the airway in a controlled environment. Physical examination (especially of the throat) and cannulation or venipuncture should be deferred, because emotional upset and crying may precipitate complete airway obstruction. When epiglottitis is suspected clinically, the child (and parents) should be approached in a calm and reassuring manner. Oxygen should be given, even if the mask is held at a distance from the child's face. The child should be taken to the operating room, anesthetic room, or pediatric intensive care unit, and held by a parent. The child should also be accompanied by a senior medical team that is skilled in airway management and carrying a laryngoscope, an endotracheal tube, needle cricothyroidotomy kit, and a percutaneous tracheostomy tray. If complete airway obstruction develops suddenly, performance of a Heimlich maneuver may relieve the obstruction temporarily; alternatively, forward traction may be applied to the mandible.

Inhalational induction of anesthesia is preferred. Laryngoscopy should then be performed and the diagnosis confirmed, based on the appearance of the epiglottic region, as described earlier in the chapter (erythema and edema of the supraglottis). Endotracheal intubation is then achieved using an orotracheal tube, which is later changed to a nasotracheal tube, because this is less likely to be displaced leading to a potentially disastrous extubation. Intubation may be done using the Seldinger technique over a bronchoscope. Although tracheostomy is rarely necessary, a surgical team should be prepared to perform this immediately if intubation is unsuccessful. Once the airway is secured, the emergency is over, and the remaining studies can be performed. Intravenous cannulation and blood sampling can be done. The white cell count is increased, and blood culture findings are often positive (70% in one series).[52] Airway secretions and swabs from the epiglottic region should be sent for bacterial culture and viral detection. Urinary antigen testing may be useful for those already receiving antibiotics.[59]

Some authors have advocated the use of a lateral neck radiograph if the child is stable before intubation, claiming it to be the "single most useful study."[2,6] We strongly disagree, and this is not our recommendation, because it can precipitate respiratory arrest as a result of complete obstruction. We take the same view as Goodman and McHugh, who state that "plain radiographs have no role to play in the assessment of the critically ill child with acute stridor."[62]

Once the airway is secured, intravenous antibiotics are started which must cover HiB and *Streptococcus;* the response is usually rapid.[2] A third-generation cephalosporin (e.g., ceftriaxone or cefotaxime) is usually given and may be changed once antibiotic sensitivities are available. Antibiotics have traditionally been given for 7 to 10 days; however, a randomized controlled trial showed that a two-dose course of intravenous ceftriaxone was as efficacious as 5 days of intravenous chloramphenicol.[59] Contacts of patients with HiB should be given appropriate prophylaxis, usually rifampicin (patients must be warned about orange secretions [e.g., tears, urine], and also that oral contraceptives can be inactivated, and the fact that this warning has been given should be recorded). There is some empiric evidence that corticosteroids may improve the course of epiglottitis, but racemic epinephrine has not been shown to be of benefit. The duration of intubation for epiglottitis due to HiB averages 1 to 3 days,[6,52] but it is longer when caused by *Streptococcus*[3]; as always, there is great individual variation. A decision to extubate may be made when an air leak develops around the endotracheal tube, but repeat endoscopy may be useful to aid this decision. Again, facilities for emergency tracheostomy must be available. Some give dexamethasone before extubation to reduce post extubation stridor.[4]

# Bacterial Tracheitis

Bacterial tracheitis has also been known as bacterial, or membranous LTB; nondiphtheritic laryngitis with marked exudate; and pseudomembranous croup.

## Epidemiology

Bacterial tracheitis is a rare disease, with a large case series (from 1998) describing only 46 cases.[63] The estimated annual incidence is 0.1 case per 100,000 children.[63] The peak incidence is during fall and winter (consistent with its postviral etiology), and it predominantly affects children 6 months to 8 years of age (mean 5 years of age). Most affected children were previously well, but it has been reported as a complication of elective tonsillectomy and adenoidectomy.[64] A large case series of life-threatening upper airway infections from Vermont in the United States between 1997 and 2006 showed that bacterial tracheitis has now superseded viral croup and epiglottitis, and was three times more likely as a cause of respiratory failure than the other two diagnoses combined.[65]

## Etiology

The most common pathogen is *S. aureus*, although other organisms implicated include HiB, α-hemolytic *Streptococcus, Pneumococcus,* and *M. catarrhalis.*[6] Occasionally, gram-negative enteric organisms and *Pseudomonas aeruginosa* are isolated (the latter is associated with a more severe clinical course).[66] In one case series, *M. catarrhalis* (27%) was more common than *S. aureus* (22%), although this represents data from a single center over the course of 14 months.[67] One series of 94 cases over 10 years found that *M. catarrhalis* was associated with a greater rate of intubation: 83% versus 49% with other organisms, although they were a younger group.[68] In addition, PIV and influenza viruses are commonly isolated from tracheal secretions; measles and enteroviruses have also been detected. Although it may be a primary bacterial infection, bacterial tracheitis is considered secondary to primary viral LTB. Presumably, viral injury to the tracheal mucosa and impairment of local immunity predisposes to bacterial superinfection.

## Pathology

Bacterial tracheitis is characterized by marked subglottic edema, with ulceration; erythema; pseudomembranous formation on the tracheal surface; and thick, mucopurulent tracheal secretions. The thick exudate and sloughed mucosa frequently obstruct the lumen of the trachea and the main-stem bronchi.[2] The epiglottis and arytenoids are usually normal in appearance, although epiglottitis and bacterial tracheitis may coexist. Tracheal stenosis can be a complication, especially after prolonged intubation.[66]

## Clinical Features

The clinical picture is initially similar to that of viral LTB, with mild fever, cough, and stridor for several days. However, the patient's condition deteriorates rapidly, with a high fever and often a toxic appearance, with respiratory distress and airway obstruction. Other symptoms include choking episodes, orthopnea, dysphagia, and neck pain.[67] The clinical picture differs from that of epiglottitis in that its onset tends to be more insidious. Patients have a substantial brassy cough, are more able to lie flat, and tend not to drool (see Table 23.1).[6] Children are more ill than with simple viral LTB and do not respond to expected therapies (e.g., corticosteroids or nebulized epinephrine). There may be other coinfections, particularly pneumonia. Other reported complications include cardiopulmonary arrest, with subsequent hypoxic encephalopathy and seizures, pneumothorax, subglottic stenosis, septicemia, toxic shock syndrome, pulmonary edema, and adult respiratory distress syndrome.[69]

The white blood cell count shows polymorphonuclear leukocytosis, often with a left shift. A lateral neck radiograph may show a hazy tracheal air column, with multiple luminal soft tissue irregularities due to pseudomembrane detachment from the soft tissue, but radiographs should be taken only after the patient is stabilized and safe. There are, however, no clinical or radiographic features capable of confirming the diagnosis.[2] This must be confirmed by upper airway endoscopy and a positive bacterial culture.

## Management

Diagnostic rigid endoscopy, which should be done under general anesthesia, is also therapeutic because it enables removal of secretions and sloughed tissue from the airway lumen; sometimes the procedure must be repeated. Many patients (especially younger ones) require endotracheal intubation and mechanical ventilation to overcome airway obstruction (reports of 50% to 100% intubation rates),[70] usually for 3 to 7 days. Frequent tracheal suction is necessary. In a 1998 case series, 57% of patients required intubation, which is lower than the rate previously reported.[67] The decision to extubate is based on clinical improvement, with reduction of fever, decreased airway secretions, and development of an air leak around the endotracheal tube. Corticosteroids may be given before extubation. Tracheostomy is required less often than in the past. There has been a case reported that was successfully managed with extracorporeal membrane oxygenation (ECMO) required for bilateral pneumothoraxes and pneumomediastinum.[71] Initially, intravenous broad-spectrum antibiotics are given, and these can be refined once cultures and antibiotic sensitivities are known, usually for 10 to 14 days. Mortality is now uncommon, estimated at 3%.[63]

# Diphtheria

## Epidemiology

Diphtheritic laryngitis was once the most common infectious cause of acute upper airway obstruction in children. In the 1920s, in the United States, there were up to 200,000 cases and nearly 15,000 deaths per year due to diphtheria.[72] Although it became uncommon due to widespread immunization programs started in the 1940s, it remains a serious disease in parts of the world. Large outbreaks occurred in the 1990s throughout Russia and the independent countries of the former Soviet Union (nearly 50,000 cases were reported). In 2005, 36 countries reported almost 13,000 cases to the World Health Organization, and 80% were from India.[73] However, in the United States, there were only five cases reported between 2000 and 2015.[72] The last childhood deaths reported in the United Kingdom were 1 in 1994 and 1 in 2008.[74] In 2013, in a refugee camp in Afghanistan, there were 50 cases and 3 deaths. Most life-threatening cases occurred in unvaccinated or inadequately vaccinated persons, and it is important for children traveling to these countries, particularly for extended periods, to be vaccinated. A list of endemic countries is available on the Centers for Disease Control website, last updated July 2015.[75] It is also important to take into account a history of recent travel in potential cases. Global coverage of a three-dose course of diphtheria-tetanus-pertussis vaccination is estimated to be 86% in 2014.[76] Adults are particularly at risk because protective levels of diphtheria antibodies decrease progressively with time from immunization, so reimmunization is recommended before travel. The Third National Health and Nutrition Examination Survey of US residents (1988–1994) indicated that fully protective levels (≥0.1 IU/mL) were found in 91% of children 6 to 11 years of age, but only in 30% of adults 60 to 69 years of age.[77]

## Etiology

Diphtheria is caused by toxigenic strains of the bacterium *Corynebacterium diphtheriae* and, less frequently, *C. ulcerans.* The organism may be isolated on bacterial culture of nasal and pharyngeal swabs, and serologic studies may detect antibodies to diphtheria toxin. Polymerase chain reaction can confirm *C. diphtheriae tox* genes.[72] There has been a case reported where nontoxigenic *Corynebacterium diphtheria* caused necrotizing epiglottitis in an immunocompromised child.[78]

## Pathology

Diphtheria is an acute disease, primarily involving the tonsils, pharynx, larynx, nose, skin, and occasionally other mucous membranes. In the milder, catarrhal form, there is no membrane formation, but in the more severe, membranous form, there is a characteristic lesion of one or more patches of an adherent grayish-white membrane, surrounded by inflammation. The toxin causes local tissue destruction at the site of membrane formation, which promotes multiplication and transmission of the bacteria.[79]

## Clinical Features

The incubation period is 1 to 6 days. Classic respiratory diphtheria is characterized by an insidious onset, and patients typically present with a 3- to 4-day history of upper respiratory infection. They have a fever, membranous pharyngitis with a sore throat, characteristic fetor oris, cervical lymphadenopathy, and sometimes edema of the surrounding soft tissues (bull-neck appearance). They may have a serosanguineous nasal discharge. Although not always present, the membrane is typically gray, thick, fibrinous, and firmly adherent, so it may bleed on attempted removal (Fig. 23.4). Laryngeal diphtheria most commonly occurs as an extension of pharyngeal involvement in children, leading to increasing hoarseness and stridor. The patient appears toxic, with symptoms of LTB, and signs of severe airway obstruction may develop quickly if the pharyngeal membrane dislodges and obstructs the airway. Complications include secondary pneumonia and toxin-mediated disease including myocarditis or cardiomyopathy, neuritis or paralysis, and adrenal failure with hypotension.[74] Cardiomyopathy can be predicted from a combination of a pseudomembrane score greater than 2 (range is up to 4) and a bull-neck appearance.[80] Case fatality rates vary and can reach 20%, but the mortality rate was only 3% in a series of 676 patients (30% younger than 15 years of age) reported from the 1995 Kyrgyz Republic outbreak.[81] Deaths are usually a result of airway obstruction, myocarditis/cardiomyopathy, or sepsis (disseminated intravascular coagulation and renal failure).

Clinical characteristics and management of 676 hospitalized diphtheria cases. Kyrgyz Republic 1995. *J Infect Dis.* 2000;181[suppl 1]:S110-S115. Photograph by P. Strebel.)

## Management

Because diphtheria is now rare, a high index of suspicion is important to make the diagnosis and institute prompt treatment. Patients should be strictly isolated. Diphtheria antitoxin, which is a hyperimmune equine antiserum (available from the Centers for Disease Control and Prevention), should be administered without waiting for laboratory confirmation because it neutralizes circulating toxin, but not toxin bound to tissues. Antibiotics are not a substitute for antitoxin, but they are given to eradicate the organism, stop toxin production, and reduce the likelihood of transmission.[79] Intravenous penicillin or erythromycin is used, and once the child can swallow comfortably, treatment can be given orally, for a total of 14 days.[79] Mechanical ventilation and tracheostomy may be required. Intravenous dexamethasone has been given to children with laryngeal diphtheria and airway obstruction, and a small case series suggested that it was beneficial.[82] Because the disease may not confer immunity, patients should be given a diphtheria toxoid-containing vaccine during convalescence. Antibiotic prophylaxis (penicillin or erythromycin) is recommended for close contacts after nasal and pharyngeal specimens are taken, and immunization should be given to those who have not been vaccinated in the preceding 5 years.[79]

# Retropharyngeal Abscess

## Epidemiology

The majority of cases occur in children younger than 6 years of age, probably due to the fact that retropharyngeal lymph nodes are so abundant at this age (they tend to atrophy later in life). Analysis of the US-based Kid's Inpatient Database (KID) for 2003 covering 36 states revealed 1321 admissions with a mean age of 5.1 years, and 63% were boys; there were no deaths reported.[83] Another large series reported a median age of 3 years, with 75% of those affected younger than 5 years of age and 16% younger than 1 year of age.[84] In a large series from 1995 to 2006, there was a linear increase in incidence through the period.[85] The KID database has extended this and found a significant increase in incidence of retropharyngeal abscesses from 0.10 per 10,000 in 2000 to 0.22 in 2009, although the overall incidence of pediatric deep space neck infections has not changed.[86] The reason for this increase in the United States is unknown, but it has been thought that perhaps it is due to a change in bacterial flora (especially community-acquired methicillin-resistant *Staphylococcus aureus* [MRSA]),[87] and perhaps artifactual due to the increased use of diagnostic computed tomography (CT) scanning. Additionally, in England it has been suggested that the 39% rise in retropharyngeal and parapharyngeal abscess admission rate (children and adults) between 1996 and 2011 may be correlated with the National Health Service drive to reduce tonsillectomies in that same period, which resulted in a 41% fall in overall tonsillectomy rate.[88]

## Etiology

Retropharyngeal abscesses generally result from lymphatic spread of infection, although direct spread from adjacent areas, penetrating pharyngeal trauma (e.g., a fall with a pencil in the mouth), or foreign bodies can also play a role.[6] It has also been reported as a complication of adenoidectomy and adenotonsillectomy.[89,90] Infection is usually due to mixed flora, including *S. aureus* (methicillin-sensitive and resistant), various streptococcal species (in particular group A beta-hemolytic *Streptococcus*), HiB, and anaerobes.[84] A case has been reported due to tuberculosis (cervical Pott's disease).[91]

## Pathology

The retropharyngeal space (between the posterior pharyngeal wall and the prevertebral layer of deep cervical fascia) contains loose connective tissue and lymph nodes that drain the nasopharynx, paranasal sinuses, middle ear, teeth, and adjacent bones. The space extends from the base of the skull down to vertebra C7 or T1. Acute bacterial infection in this region may start as retropharyngeal cellulitis with localized edema of the tissues, which can progress to purulent inflammation of the tissues and retropharyngeal adenitis. However, when this process is caused by lymphatic spread, it starts as adenitis. If liquefaction of one of the nodes occurs, an abscess can form and is usually contained within the inflammatory rind of the infected node.

## Clinical Features

Presentation is often nonspecific, and there may be overlap with the presentation of croup, epiglottitis, tracheitis, and peritonsillar abscess (see Table 23.1).[6] Children with acute epiglottitis tend to appear more toxic and progress to respiratory distress more rapidly.[92] Excluding causes secondary to foreign bodies or trauma, patients usually have a history of a viral upper respiratory infection that lasts several days and then worsens. Children then have high fever, sore throat, dysphagia, poor feeding, neck pain, and stiffness. Limitation of neck extension and torticollis are more common than limited neck flexion.[84] Although the occurrence of neck signs with fever may suggest meningitis, affected children tend not to be as toxic as those with meningitis. Further deterioration may lead to extrathoracic airway compromise, with drooling, stridor, and respiratory distress. The classical picture of stridor and airway obstruction seems to be less common now, and in a series of cases reported by pediatricians from 1993 to 1998, only 3% of 64 children in Salt Lake City had stridor or wheezing.[84] However in a series of cases from 2002 to 2007 from the same center, but published by the otolaryngologists, 14/130 (11%) presented with airway obstruction, and 50% required intubation, with an average age of 1.4 years.[93] Older series have reported a higher incidence of stridor. Reported rates include 71% in patients younger than 1 year of age, 43% in patients older than 1 year of age, and no stridor in those older than 3 years of age in a series of 31 children in Sydney, Australia[94]; a rate of 56% in 17 patients in Denver[95]; and a rate of 23% in 65 children in Los Angeles.[96] It is possible that the spectrum of disease is changing, but it is more likely that the diagnosis is being made earlier, before the airways are compromised.[84] Sometimes a retropharyngeal mass is visible in the mouth, seen as an asymmetrical bulge of the posterior pharyngeal wall (Fig. 23.5), or a neck mass (marked lymphadenopathy or parapharyngeal abscess) is visible and palpable. Complications include rupture of the abscess with aspiration, asphyxiation or pneumonia, extension to a mediastinal abscess with or without mediastinitis, and Lemierre syndrome with vascular complications (e.g., anaerobic septic thrombophlebitis of the internal jugular vein with multiple septic pulmonary emboli, and potential erosion through the carotid artery sheath).[89,92]

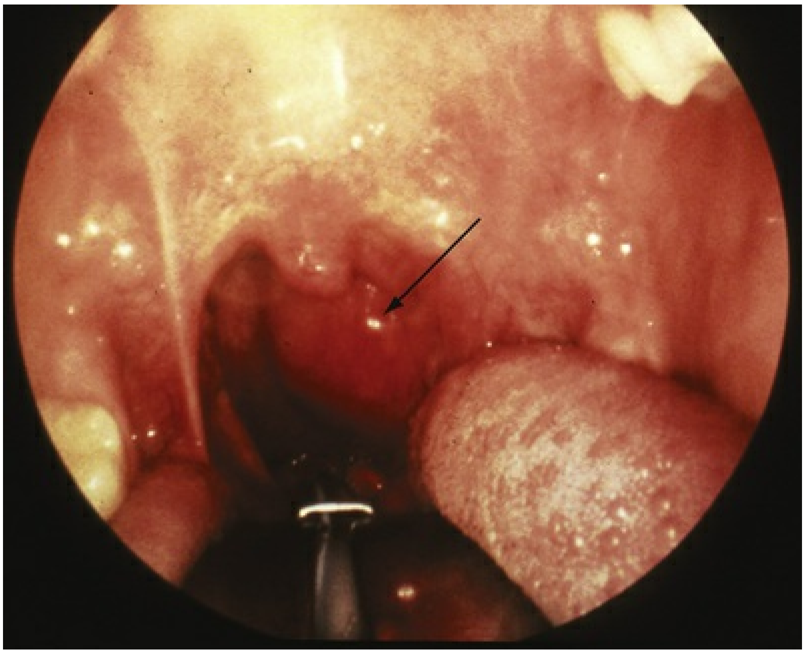

**FIG. 23.5** Retropharyngeal abscess behind and to the left of the uvula *(arrow)* is shown. The tongue is pressed down and to the left with a tongue depressor. (Photograph courtesy of the Otolaryngology Teaching Set, Department of Ear, Nose & Throat, Great Ormond Street Hospital for Children NHS Trust, London.)

Once the child is stable and safe, a lateral neck radiograph with the neck in full extension may confirm the diagnosis. Widened prevertebral soft-tissue shadow and air-fluid levels in the retropharyngeal space are all indicators.[6] The radiograph must be taken in the correct position (true lateral orientation, with the neck in extension, and if possible, during full inspiration) to ensure that the retropharyngeal space is not falsely thickened.[84] A contrast-enhanced computed tomography scan is useful because it differentiates a fully developed abscess from cellulitis and delineates the full extent of the abscess. Blood cultures findings are usually negative, but the white blood cell count will be increased.

## Management

Traditionally, management involves surgical drainage of the abscess (plus antibiotics). However, more cases are being managed by intravenous antibiotics alone, although surgery must be considered early if there is a compromised airway. Percutaneous CT-guided aspiration has also been described.[97] In one older series, 25% of patients required no surgery,[95] but in the Salt Lake City series that covered 1993–1998, 58% of 64 patients had antibiotics alone, with no treatment failures.[84] Data from KID 2003 (discussed earlier in the chapter) showed that 43% of cases admitted required surgical drainage.[83] Update of the KID database shows that surgical management has continued to fall to 38% in 2009.[86] Many children start treatment with antibiotics before the diagnosis is made, and certainly retropharyngeal cellulitis can be treated with antibiotics alone. When necessary, surgical drainage is performed through the intraoral route. Care must be taken to avoid aspiration of the infected material. Occasionally, if there is extension lateral to the great vessels, external drainage through the neck is necessary. Mortality is rare now, with no deaths in recent reports.

# Peritonsillar Abscess (Quinsy)

## Epidemiology

Peritonsillar abscess is the most common deep-space head and neck infection in both adults and children. However, it is more common in young adults than in children. It tends to affect older children and adolescents, and in one large, 10-year series, the mean age was 12 years of age, with two-thirds of those affected older than 10 years of age.[98] In this series, 62% of cases occurred on the left side versus 38% on the right (with no obvious explanation).[98] There is no seasonal predilection. The reduction of antibiotic prescribing to children by general practitioners in the United Kingdom from 1993 to 2003 has not been accompanied by an increase in hospital admissions for peritonsillar abscess.[99] The KID database in the United States found no significant change in incidence of peritonsillar abscess between 2000 and 2009 (0.82 to 0.94 per 10,000 children).[86] In England, there was a 31% rise in peritonsillar abscess admission rate for children and adults between 1991 and 2011, that was thought to be associated with the 41% fall in overall tonsillectomy rate in that same period.[88]

## Etiology

A peritonsillar abscess is usually a complication of acute tonsillitis, but it may follow pharyngitis or a previous peritonsillar abscess. The infection usually involves mixed bacterial flora, with *Streptococcus pyogenes* as the predominant organism. In a small series of children younger than 5 years of age, *Streptococcus viridans* was the most common organism detected.[100] In a large series of 457 children and adults in Israel, while *S. pyogenes* was the most common organism isolated, there was a sharp rise in anaerobes cultured, particularly *Prevotella* and *Peptostreptococcus*.[101]

## Pathology

Peritonsillar abscess is believed to arise from the spread of infection from the tonsil or the mucous glands of Weber, located in the superior tonsillar pole.[98] There is a spectrum of peritonsillar cellulitis that may then result in a collection of pus located between the tonsillar capsule (pharyngobasilar fascia), the superior constrictor, and the palatopharyngeus muscle.[98] There is a risk of spread through the muscle into the parapharyngeal space or other deep neck spaces. The abscess pushes the adjacent tonsil downward and medially, and the uvula may be so edematous, as to resemble a white grape.

## Clinical Features

The child who is already affected by acute tonsillitis becomes more ill with a high fever and has a severe sore throat or neck pain, as well as marked dysphagia with referred earache. Absent or decreased oral intake can lead to dehydration, particularly in younger children.

Cervical lymphadenopathy is almost always present. The uvula is edematous and deviated to one side, and there is fetor oris. A striking feature may be trismus, with limited mouth opening. Examination may be difficult in a young, uncooperative child who refuses to open the mouth. The white blood cell count will be elevated.

The relevance of this condition to pediatric pulmonologists is that acute enlargement of the tonsils can cause airway compromise, and a ruptured abscess can lead to aspiration of infected material and subsequent pneumonia. In one large series of 169 children under 18 years of age, 8% presented with airway compromise.[102]

## Management

Children may need intravenous fluids. Antibiotics are necessary, and intravenous penicillin is as effective as broad-spectrum antibiotics, although additional anaerobic coverage should be considered.[103] Analgesia is important. Corticosteroids are not uncommonly used but are of no obvious benefit (or harm).[102] Treatment often involves needle aspiration or incision and drainage; a meta-analysis of 10 studies with 496 patients revealed an average 94% success rate with simple needle aspiration.[104] The KID database revealed that about a third of cases required incision and drainage in 2009, with an increase over the decade (26% to 34%).[105] Nevertheless, an initial period of medical treatment is appropriate in the absence of airway compromise and systemic toxicity, especially in younger children.[106] One case series of 88 children from Korea suggested that younger age (<7.5 years), fewer episodes of acute tonsillitis, and smaller abscess size predicted successful nonsurgical treatment.[107] There is some debate among otolaryngologists about the role and timing of tonsillectomy, and peritonsillar abscess is no longer considered an absolute indication for tonsillectomy, although a history of recurrent tonsillitis prior to developing the peritonsillar abscess leads to a higher recurrence rate.[108] In the United States, the KID database found a significant reduction in tonsillectomy carried out between 2000 and 2009 (13% to 8% cases).[105] In a large nationwide study from Taiwan of almost 29,000 cases of peritonsillar abscess, the recurrence rate was 5% and was associated with the incidence of prior episodes of tonsillitis in all ages, and management by needle aspiration (vs. incision and drainage) in children.[109]

# Infectious Mononucleosis

Infectious mononucleosis is caused by Epstein-Barr virus (EBV) and is common in adolescents and young adults. The clinical syndrome is characterized by fever, fatigue, malaise, lymphadenopathy, and sore throat. Diagnosis is confirmed by positive EBV serology, and positive heterophile antibodies (Monospot), although the latter are only positive in 50% of children and 90% of adults. The illness is usually self-limiting, but malaise and exhaustion can persist.

Some degree of airway obstruction is not uncommon (reported in 25% to 60% cases),[74] but significant airway compromise is rare, occurring in an estimated 1% to 3.5% cases.[110] Nevertheless, given the high frequency of EBV infection, this small proportion still represents many patients. Acute upper airway obstruction may occur, but the cardinal signs of acute obstruction (stridor and respiratory distress with recession and tachypnea) can be absent until late in the process.[111] Obstruction arises from a combination of inflammation and hypertrophy of the palatal and nasopharyngeal tonsils, edema of the pharynx and epiglottis, and pseudomembrane formation in the large airways.[112] Acute onset of obstructive sleep apnea has also been described in a child who required continuous positive airway pressure when asleep, until recovery after 3 days.[113] Peritonsillar abscess formation is a rare complication that can further compromise the airway, and it is now believed that this is not significantly associated with the use of corticosteroids, which contradicts earlier reports.[114]

Management is with systemic corticosteroids (in the presence of obstruction) and supportive care, which may include ventilation. A tracheostomy is sometimes necessary, as the severity of the inflammation in the oropharynx can make intubation difficult. If corticosteroids do not help, the role of acute tonsillectomy has been advocated,[115] but it is controversial due to the high risk of perioperative bleeding.[112]

# Bronchiolitis

*Steve Cunningham MBChB, PhD*

## Epidemiology

Bronchiolitis is the most common lower respiratory tract infection in children. The condition forms part of the spectrum of viral lower respiratory tract infection that includes bronchiolitis, viral pneumonia, and viral-induced wheeze. In polar hemispheres (north and south), bronchiolitis is a seasonal disease, dominating winter months, with a peak over 6 to 8 weeks around the winter solstice. In tropical climates, the disease is associated with rainy months and is seasonally more dispersed.[1] Climate and environment appear to influence both season and severity.[2,3]

Bronchiolitis is diagnosed clinically by integrating characteristic but variable signs and symptoms across a broad age range, though the majority of cases occur in children under 1 year of age. The condition can be caused by any respiratory virus and has a wide spectrum of disease severity.[4]

A "classic" case would be an infant aged 3 to 5 months of age[5] who develops coryza and over the subsequent 3 to 4 days has increased difficulty with breathing, and consequent inability to maintain adequate oral feeding. Wheeze or crackles can be heard on auscultation. Improvement occurs by days 5 to 7, though a characteristic harsh cough may persist for 21 days or more.[6,7]

While the diagnosis often appears straightforward, the wide range of disease severity across a skewed but broad age range and the need for clinical diagnosis (with associated inconsistency) creates difficulty in establishing precise data.[8] In addition, while bronchiolitis is a clinical diagnosis applied to any infecting agent, the majority of data available relate to bronchiolitis caused by respiratory syncytial virus (RSV) infection; and within RSV bronchiolitis is a focus on those at high risk, in particular, those born prematurely. Reference to these groups synonymously with bronchiolitis can make interpretation of epidemiological data difficult and may reduce the understanding of bronchiolitis caused by non-RSV and in lower risk patients (particularly children born at term).

## Population Risk for Bronchiolitis Associated With All Respiratory Viruses

There are only limited estimates of population risk for bronchiolitis associated with all respiratory virus infections, but approximately 40% of infants are affected by bronchiolitis in the first year of life.[9] In the United Kingdom, using primary care databases, the 1 year incidence of children given a specific diagnosis of bronchiolitis is 58 to 65 per 1000 children,[8,10] rising to 204 per 1000 when a broader definition of bronchiolitis was used to capture potential cases.[8] This study highlights that in children with typical lower respiratory tract signs and symptoms, clinicians may not ascribe the discrete diagnosis of bronchiolitis; a finding also found in other countries such as Spain[11] and across health care systems,[12] with evidence that a diagnosis of bronchiolitis is more likely to be made in secondary than primary care. The hospital admission rate for bronchiolitis in children without high-risk conditions is 1.9% in the United States using coded hospital data,[13] showing a decline from 2.7% in the period 2000–2009. In contrast, UK data suggest that admission rates are continuing to increase over time (to 4.0% in 2011).[14] Of those admitted to hospital, 85% are born at term and 15% are born preterm.[15] Additional factors also place children at higher risk of admission including, age (<3 months), male sex, being bottle-fed, multiple birth, and family smoking. Rates of admission for infants with a diagnosis of bronchiolitis can vary up to threefold across hospitals in the same country.[14] Duration of admission is also highly variable within countries and internationally.[16]

Mortality for bronchiolitis is low[17]; United States 0.03% overall, with an adjusted odds ratio (OR) of 0.25 for mortality in children less than 1 year of age without previous health condition and primary diagnosis of bronchiolitis.[13] Admissions to intensive care have remained constant over time[14] although related costs are increasing.[13]

## Population Risk for Respiratory Syncytial Virus Bronchiolitis

RSV infects 69% to 98% of infants in the first year of life.[18,19] The rapid development of vaccines and treatment therapies for RSV has added impetus to the need to better define the burden of RSV disease. Globally there are an estimated 33.8 million cases of RSV lower respiratory tract infection each year in children under 5 years of age, resulting in 3.4 million admissions to the hospital and 66 to 199 thousand deaths (with the majority in low- and middle-income countries).[20]

In the United States an estimated 20% of children will attend primary care each year with RSV bronchiolitis, and up to 7% attend an Emergency Department (ED).[21] Admission to hospital with RSV bronchiolitis is typically around 2.4% of all infants,[15,22] though in previously healthy term infants, the admission rate to hospital with RSV bronchiolitis can be as low as 0.7%.[23]

## High-Risk Population for Bronchiolitis Associated With All Respiratory Viruses

In infants who are born preterm at 32 to 35 weeks' gestation, 48% will develop bronchiolitis and 6% require admission to the hospital.[24] The risk of bronchiolitis is increased in a range of conditions compared with term infants, including preterm birth (respiratory rate [RR] 1.89), cystic fibrosis (RR 2.45), congenital heart disease (RR 3.35), chronic lung disease (RR 1.61), immunodeficiency (RR 1.73), Down syndrome (RR 2.53), and cerebral palsy (RR 2.43).[25,26]

## High-Risk Population for Respiratory Syncytial Virus Bronchiolitis

For infants born ≤ 32 weeks gestation, 75% of infants will have a lower respiratory tract infection in the first year of life, with 35% RSV positive and 40% RSV negative; of these infants, 41% of RSV positive will be admitted to the hospital versus 18% of RSV negative.[27] Recent studies suggest that hospitalization rates for high-risk infants due to RSV are reducing over time and are now similar to those for RSV negative, possibly as a result of improvements in neonatal care or immunoprophylaxis in high-risk groups (Fig. 24.1).[28,29] Risk of death is much higher amongst high-risk groups who are RSV positive, including preterm (1.2%), congenital heart disease (5.2%), and bronchopulmonary dysplasia (7.0%).[17]

Trends in respiratory syncytial virus and bronchiolitis hospitalization rates in high-risk infants in a United States Nationally Representative Database, 1997–2012. *PLoS One.* 2016;11(4):e0152208.)

# Etiology

Bronchiolitis has a viral etiology, with RSV the most common cause, reported in 43% to 75%[30,31] of cases. Other viruses associated with bronchiolitis are human rhinovirus (18%), influenza, coronavirus, human metapneumovirus, adenovirus, parainfluenza virus and human Boca virus[30,31]; that is, "any respiratory virus."

RSV has two strains, A and B, with RSV A associated with more severe disease.[32,33] Reinfection in the same season with the same or different strain is possible.[34] As a sole infecting agent, RSV is associated with more severe bronchiolitis than other single respiratory virus infections.[5] Coinfection of RSV with rhinovirus can produce even more severe disease.[35] RSV is the most common infectious agent in children admitted to the hospital with radiological features consistent with pneumonia (occurring in 28% of children—most commonly those under 5 years of age).[36] In young children who are well immunized, RSV represents the most common cause of lower respiratory tract infection.[37]

# Pathology/Pathogenesis

What commences as an upper respiratory tract infection becomes a lower respiratory tract infection over the course of 2 to 5 days. Infants are particularly susceptible as they have small bronchi that are more likely to become blocked by secretions and edema, and a less well-developed ability to respond to and clear viral infection.[38]

Histopathology is naturally limited to the most severe cases who have died, where the bronchioles are edematous and blocked by necrotic epithelium and neutrophils, with some mucus binding this debris together.[39] Airway obstruction is intensified by poor airway clearance associated with loss of cilia function occurring within 24 hours and persisting for up to 3 months after the illness.[40] Destruction of cilia is considered to be caused by virus replication and not mediated by inflammation.[38] RSV is associated with more severe airway pathology than that found in children dying from other respiratory viruses, even in those not mechanically ventilated.[39]

Viral shedding is higher and more prolonged in younger infants and those with more severe disease.[41] Increased disease severity, longer hospital stay and use of intensive care is associated with higher viral load for RSV in nasopharyngeal secretions.[42,43] Severity of disease is associated with both infant risk factors (including lack of adaptive T cell response),[26,44] but also RSV virus specific factors (viral antigen load and direct cytotoxic effects).[45] Determining the relative contribution of both of these to disease severity will be important; if the latter is dominant, antiviral agents provided early in the course of the disease may reduce severity, whereas dominance of the former might need additional immunomodulators.[4]

Biomarkers are now sought to better characterize those at risk of greater disease severity and to indicate recovery. Infants hospitalized with RSV bronchiolitis have increased interleukin (IL)-33 and IL-13 in secretions.[46] Polymorphisms of surfactant protein A are associated with increased risk of intensive care admission.[47] Cysteinyl leukotrienes are increased in infants with RSV bronchiolitis and are still increased 1 month following infection.[48] More severe disease is also associated with increased serum cathelicidin,[49] lactate dehydrogenase, caspase[50] and IL-15.[51] There is some evidence that more severe disease may be associated with an insufficient inflammatory response.[52] The interrelationship of the microbiome in bronchiolitis is also being actively explored.[53]

# Clinical Features

Bronchiolitis is diagnosed clinically. Variance in the clinical interpretation of symptoms and physical findings lead to inconsistency in diagnosis, particularly in milder cases and children over 1 year of age.

## Symptoms

Typical symptoms are rhinorrhea, proceeding over 2 to 4 days to a characteristic harsh moist cough with pyrexia that is typically below 39°C, although fever above 38.5°C is seen in 50% of infants.[54] Ability to achieve adequate oral feeding declines as nasal obstruction with secretions develops and work of breathing increases. The time to peak symptoms of 4 days is associated with the peak in viral load,[42,55] varying from infant to infant.

In younger children (particularly <6 weeks of age), apnea may be a presenting sign, sometimes in the absence of other features of bronchiolitis. Apnea may be temporarily improved by nasal suctioning, but it is most likely a direct viral effect in young infants.[56] Apnea is a “red flag” sign in bronchiolitis that warrants a period of review in a supervised clinical setting to ensure that it has resolved.

Patients more likely to require intensive care include preterm infants and those with apnea, low birth weight, or a respiratory rate greater than 70/min.[57,58] Children tend not to relapse during the improving phase of the illness, which should give confidence to clinicians when considering discharge from ED or hospital.[58,59]

## Physical Findings

Physical findings include an increased respiratory rate, chest recession, use of accessory muscles, hyperinflation, wheezing, crackles, and reduced arterial oxygen saturations.[60] Physical findings vary depending on sleep state (and associated changes in tidal volume). Respiratory rate is a key marker of disease severity, with ≥60/min considered severe and ≥70/min critical.[26,61] Oxygen saturation may be improved (at least temporarily) by removal of nasal secretions.[62]

## Clinical Scores

Bronchiolitis is a highly variable disease that requires assessment of disease severity by clinicians for decision making, some of which is subjective. Clinical scoring systems have been developed in an attempt to standardize care and minimize variance. Many early scores derived from asthma scores. The most commonly applied scores for bronchiolitis are outlined in Table 24.1. Within this table, the most widely quoted is the Respiratory Distress Assessment Instrument (RDAI)[63] (and the resulting Respiratory Assessment Change Score, RACS). More recent scores were developed to have more detailed validation (Liverpool Infant Bronchiolitis Severity Score–Proxy Reported Outcome Measure [LIBSS PRO][64] and

Genetics, Vaccines and Infectious Diseases Paediatrics Research Group [GENVIP][65]) and to improve the ability to identify those at risk of deterioration. The ability of clinical scores to retain precision and reliability, when scoring is performed by larger numbers of health care professionals in the context of multicenter Phase III trials, is of current interest.

## Table 24.1

### Clinical Scores for Bronchiolitis

| **Score** | **Tal**[a] | **Lowell**[b] | **Wang**[c] | **Wilson**[d] | **Jacobs**[e] | **Liu**[f] |
|---|---|---|---|---|---|---|
| Name | Tal and later Modified Tal ($SpO_2$ not cyanosis) | Respiratory Distress Assessment Instrument (RDAI) | No names | Comprehensive Severity Index (pediatric component) | Canadian Acute Respiratory Infection and Flu Scale (CARIFS) | No name |
| General respiratory or bronchiolitis specific | General | General | General | General | General | General |
| Date published | 1983 | 1987 | 1992 | 2000 | 2000 | 2004 |

# Disease Severity

Symptoms in bronchiolitis vary across a wide but skewed continuum from mildly increased work of breathing with cough to respiratory failure and death. Often divided into mild, moderate, and severe disease, the perspective on these gradations varies across health care systems. A World Health Organization (WHO) workshop has provided candidate definitions differentiating a diagnosis of RSV lower respiratory tract infection ($SpO_2$ <95%) from severe (<93%) and very severe RSV disease ($SpO_2$ <90%, inability to feed orally, or reduced level of consciousness).[66] Infants can display variance in $SpO_2$ within this range (90% to 95%) over short periods of observation without significant change in clinical status,[58,62,67] which may limit the discriminatory reliability of these definitions. From a secondary care perspective, moderate severity is often considered a need for admission to hospital and severe by need for critical care (positive pressure support). Clinical scores are often designed to identify transition points in the level of care required.[64] The currently available evidence concerning transition points in level of care is poor. Treatment guidance, particularly benefit from use of interventions at the ED/Ward (i.e., $SpO_2$)[68] and ward/critical care floor interface (i.e., high-flow nasal cannula [HFNC] oxygen and continuous positive airway pressure [CPAP]) is much needed. Guidelines have provided signs and symptoms that should alert clinicians to a child at risk of deterioration and suggested criteria for admission to the hospital.[26] In hospitals, those most likely to deteriorate to the extent of being provided with critical care support are of lower birth weight (<5 lbs, 2.25 kg) and/or have a respiratory rate ≥70/min on day 1 of admission.[57]

## Imaging, Laboratory Findings

Chest radiography is not required to confirm a diagnosis of bronchiolitis. A chest radiograph often leads to increased diagnostic uncertainty as the features may be similar to those of pneumonia (atelectasis, mucous plugging, and loss of volume) and consequently lead to greater inappropriate use of antibiotics.[69] Chest radiography should be reserved for a child who is atypical, for example, showing persistently focal crackles, a temperature remaining above 39°C despite antipyretics, or respiratory failure requiring critical care support.[26,70]

Laboratory tests do not aid in the clinical diagnosis of bronchiolitis. Serious bacterial infection is unusual and complete blood counts and blood cultures are unhelpful (though recent evidence suggests that although still uncommon, it may be more frequent than previously considered).[65] Dehydration is usually mild and best assessed clinically without electrolyte measurement. Approximately 6% of infants with bronchiolitis can have concurrent urinary tract infection, so urine culture may be of value in persistently febrile infants, particularly those under 3 months of age.[71]

Measurement of arterial/capillary carbon dioxide is commonly performed, but can be restricted to those children with increased respiratory rate and work of breathing despite oxygen supplementation.[72]

## Diagnosis and Differential Diagnosis

The clinical interpretation of signs and symptoms is difficult in a condition where age boundaries are loose (and skew to older ages in those with comorbidity) and symptoms vary from patient to patient and time to time. This naturally leads to variation in diagnosis and differential diagnosis. There is a common understanding that a clearer diagnosis is possible in those under 1 year of age and most guidelines reflect this. However, constraining a diagnosis of bronchiolitis to those less than 1 year of age may reduce the ability to identify the whole population of children with bronchiolitis who could benefit from potential interventions. In general, a broader definition of bronchiolitis is used in North America and Asia that captures a higher percentage of older children with wheezing, where rhinovirus is the dominant infecting agent.[73] Such children may be given a diagnosis of viral induced wheeze in other countries. There is most likely a continuum of viral lower respiratory tract infection across age ranges that moves from current diagnoses of viral bronchiolitis to viral pneumonia and viral-induced wheeze/wheezy bronchitis.[74,75]

The clinical features consistent with a diagnosis of bronchiolitis across different guidelines are presented in Table 24.2. Diagnosis has a typical onset of a viral respiratory tract prodrome proceeding to lower respiratory symptoms over 3 to 4 days. The South African guideline (2010) considers hyperinflation the most reliable clinical sign in bronchiolitis.[76] The UK guideline (2015) provides a more proscriptive definition.[26]

**Table 24.2**

**Guideline Recommendations in Bronchiolitis**

| | **Spain (2010)** | **South Africa (2010)** | **Canada (2014)** | **United States (2014)** | **United Kingdom (2015)** | **Finland (2016)** |
|---|---|---|---|---|---|---|
| Age | <24 months | Children | ≤2 years | 1–23 months | Children (mostly under 1 year) | Children (mostly under 6 months) |
| Clinical definition | Not stated | Viral URTI, with poor feeding, low-grade fever, hyperinflation of the chest, wheezing, tachypnea, lower chest wall retractions | Viral URTI, cough or rhinitis followed by some of tachypnea, costal retractions, apnea, wheezing or crackles, nasal flaring, hypoxemia | Rhinitis and cough, followed by tachypnea, wheezing, rales, use of accessory muscles and/or nasal flaring | Coryza followed by persistent cough and tachypnea or chest recession (or both) and wheezing or crackles (or both). Apnea may be presenting symptom in absence of above. | Not stated. Fine crackles on auscultation considered characteristic. |

*URTI*, Urinary tract infection.

Testing of nasal secretions for virus may help consolidate the clinical diagnosis of bronchiolitis and inform health care logistics. Most commonly used, and with highest precision, are polymerase chain reaction (PCR) diagnostics for a range of respiratory viruses, but point of care (PoC) testing for a more limited range of viruses (most often RSV) is increasingly precise and cost effective.[77] Testing for RSV (as the most common infecting agent in bronchiolitis) is often performed to aid cohorting of patients within hospitals. The increasing recognition that multiple viruses may be identified in those with acute bronchiolitis has called into question the benefit of cohorting based on RSV status.[78] PCR diagnostics may sometimes be considered oversensitive to the detection of virus fragments postinfection, and multiplex PCR results should be interpreted with this understanding.

Differential diagnosis includes bacterial pneumonia or an alternative cause of crackles, wheeze, and increased work of breathing in a young child. Persisting crackles (crepitations) in one lung zone, fixed focal wheeze, persistent pyrexia (>39°C) or persistently increased work of breathing in a child who appears otherwise recovered warrant further evaluation.

Prescient in the mind of most clinicians is that a bacterial pneumonia may be missed. Chest radiographs have similar appearances and are poor discriminators. We can assume that bacterial coinfection risk is low, as the use of antibiotics in bronchiolitis is not associated with faster recovery.[79] Further investigation could be limited to those with the persisting clinical features noted above. In children with more severe disease, there may be a role for antibiotics as bacteria are isolated in 33% to 44% of lavage samples in children with severe bronchiolitis who are intubated and ventilated.[80–82] There are no trials of outcome for antibiotic use in children with bronchiolitis receiving intensive care.

Though uncommon, congenital lesions may masquerade as bronchiolitis, and this should be borne in mind for children with atypical clinical features or those slow to recover. Congenital heart disease may present as bronchiolitis when pulmonary vascular resistance falls increasing left to right shunt. More difficult to differentiate are children with congenital (or less commonly acquired) pulmonary malformations. Fixed focal wheeze may be a sign of tracheomalacia or bronchomalacia, stenosis, or compression from lobar emphysema or a bronchogenic cyst and would warrant a chest radiograph. A slow recovering course with persistent chest signs could be an infected congenital pulmonary malformation (such as a congenital cystic adenomatoid malformation [CCAM] or sequestration). Children with persistent fine crackles, tachypnea, and low (often borderline) oxygen saturation may have an interstitial lung disease, particularly neuroendocrine cell hyperplasia (NEHI) presenting as recurrent "bronchiolitis." Young children with persistent, sometimes focal, crackles postadenovirus (though may also be other respiratory viruses and mycoplasma pneumonia) should be evaluated for postinfectious bronchiolitis obliterans (PIBO); see section 6 of the book.

## Management and Treatment

Management of bronchiolitis is supportive, assisting hydration and hypoxemia until improvement. With increased respiratory rate and nasal secretions, oral feeding is challenged, and those with severe disease require assistance with feeding by enteral or parenteral means. The threshold for supporting hydration is typically when an infant's intake is reduced to 50% to 75% of usual volume. The chosen percentage of intake depends on the child's status: an expreterm 10-week-old infant on day 3 of illness may be supported at 75% understanding that they most likely will deteriorate, whereas a robust 8-month-old term infant may be able to tolerate 50% feed volume for a couple of days until disease resolution. Nasogastric feeding is easier to administer than intravenous fluids but has no advantage in recovery from acute disease.[83]

Oxygen may be used to treat hypoxemia. The threshold oxygen saturation at which to use supplemental oxygen varies across guidelines and is typically set between 90% and 94% at sea level. In children admitted to hospital with bronchiolitis, management at a threshold of 90% $SpO_2$ is safe and as clinically effective as a 94% target.[84] The threshold oxygen saturation for admission to hospital is often 92%, as some data suggest that infants have a higher risk of desaturating further at this oxygen saturation.[85] Oxygen desaturation may however have a disproportionate influence on decisions to admit children to the hospital,[68] and much like hydration status (previously mentioned), the context of the measurement should be considered. Many infants discharged home from ED with bronchiolitis experience desaturation events subsequently that are not associated with clinical deterioration.[67] In hospitals, the use of intermittent oxygen saturation monitoring is much discussed, and though the benefit below 90% $SpO_2$ is not established, once stable above 90% $SpO_2$, oxygen saturation monitoring should be stopped.[86] Use of therapies in addition to supplemental oxygen and hydration are poorly supported by current evidence. There is some evidence that infants handled less get better quicker,[87] and the use of additional therapies should be considered with that in mind.

There is widespread variation across hospitals and countries in the management and treatment of bronchiolitis reflecting local custom and individual clinician practice.[88] Reducing variation and associated health care costs is a key aim of bronchiolitis management presented through guidelines. Guidelines for the care of infants with bronchiolitis based on systematic review and published in English are available from the United Kingdom (2015),[89] United States (2014),[90] Canada (2014),[61] Spain (2010),[91] Finland (2016),[92] and South Africa (2010),[76] which has been updated as a critical review 2016.[93] No therapies receive support across all guidelines for use with the exception of supplemental oxygen. Chest physiotherapy does not speed recovery. Antibiotics, though still widely used, are of no benefit in bronchiolitis.[79] In addition, bronchodilators are less likely to be recommended in more recent guidelines, and the theory that they may be of greater benefit in infants more likely to develop asthma has been refuted.[94] Nebulized hypertonic saline has been of benefit in cystic fibrosis and in early trials in bronchiolitis,[95] but larger well-designed trials have not demonstrated a persuasive benefit.[96–100]

Recent years have seen the increasing use of HFNC oxygen in acute bronchiolitis.[101] Though clinical trials have not yet demonstrated important clinical or physiological benefits,[102] large well-designed trials are in progress and are beginning to report.[102a,103] CPAP has some benefit in bronchiolitis, and may prevent deterioration when used early.[104] As with all management in bronchiolitis, the use of HFNC oxygen, CPAP, and intubation varies across sites irrespective of disease severity,[105] and better understanding of the risks and benefits of these interventions is required.[106]

There are no current effective pharmacological treatments for RSV. While ribavirin was previously used as an antiviral treatment for RSV, it is now considered ineffective.[107] Novel treatments for acute infection are in development: antivirals and nebulized immunoglobulin. In this rapidly moving field, it seems probable that a treatment for RSV will become available in the next 5 years.[108] Reduction in viral load has been demonstrated in adult challenge models of RSV treated with the antivirals ALS-8176[109] and GS-5806[110]

# Prevention

Prevention of spread of RSV depends on good hygiene, in particular, hand washing, as RSV may survive for up to 6 hours on surfaces contaminated by droplets.[111] Similar precautions are appropriate for other respiratory virus infections associated with bronchiolitis. Many hospitals use PoC testing for RSV to determine cohorting of infants as inpatients.[107] While this is still common, the practice is called into question by the range of coinfection with other respiratory viruses revealed by PCR panel testing; up to 62% of children with viral respiratory tract infection have more than one virus detected.[112]

Prevention of RSV (as the most common cause of bronchiolitis) has been a long-term goal. Early formalin inactivated vaccines were associated with more severe enhanced RSV disease and deaths, possibly resulting from inadequate T cell priming.[113] Subsequent vaccine development has been cautious in view of this experience.

In the 1990s, RSV intravenous immunoglobulin was developed[114,115] but was rapidly superseded by palivizumab, a monoclonal antibody delivered by monthly intramuscular injection. When administered over the RSV season, it reduces hospital admission in high-risk infants.[116] Palivizumab's monthly injections and limited efficacy have prompted the development of extended life monoclonal antibodies that are undergoing licensing trials in preterm infants.[117] They will hopefully be evaluated in the future for high-risk infants born at term.

RSV vaccine development has gained significant impetus over the last 15 years with a wide range of candidate vaccines in development both for pediatric and maternal use; maternal immunization could provide passive transplacental protection to infants in the first 3 to 6 months of life (http://www.path.org). A Phase III trial of maternal immunization by Novovax is expected to conclude in 2020.

# Prognosis

For most children, bronchiolitis is a self-limiting disease, with cough as the most persistent symptom resolving at a median of 12 to 15 days.[84,118] Many children, however, develop recurrent respiratory symptoms. In the first few months following illness, this is considered in part to result from loss of cilia from the airway epithelial surfaces during the acute illness.[40] For those who experience chronic symptoms, the debate continues on whether children with more severe bronchiolitis and recurrent postinfectious wheezing have premorbid susceptibility, with some evidence suggesting poorer preexisting lung function.[119] Recurrent wheeze in the year following bronchiolitis occurs in 62% of those who are RSV positive and 32% of those who are RSV negative.[120] Recurrent postinfectious wheeze is not reduced by montelukast[121] or inhaled corticosteroids,[122,123] but there is good evidence of benefit from Palivizumab,[124] and potentially azithromycin,[125] though the latter requires further study.

In the longer term, there is good evidence that children who have had an admission to the hospital for RSV bronchiolitis are 3 times more likely to have a diagnosis of asthma and lower lung function at age 6 years[23] and a higher incidence of asthma at age 13[126] and 18[127] years. The question remains whether such children are predisposed to bronchiolitis because of premorbid anatomy[119] and the consequent interrelationship between host and virus specific effects on the development of asthma.

# Pneumonia in Children

*Marcelo C. Scotta MD, Paulo J.C. Marostica MD, Renato T. Stein MD*

Pneumonia is broadly defined as inflammation in the lung caused by an infectious agent that stimulates a response resulting in damage to lung tissue. Different definitions for pneumonia vary from "detection of pulmonary pathogens in lung specimens" to the "presence of pulmonary infiltrates on chest radiographs," or even clinically based criteria, such as age-specific tachypnea or lower chest retractions.[1,2]

## Epidemiology and Etiology

Community-acquired pneumonia (CAP) is one of the most important health problems affecting children worldwide, and is the leading single cause of mortality in children younger than 5 years of age, especially in low- and middle-income countries. Annually, there are 4–5 million deaths reported in children younger than 5 years of age, and pneumonia is estimated to account for approximately 1 million of these.[3]

The estimated median global incidence of pneumonia in 2010 in children younger than 5 years of age was 0.22 episodes per child-year, 11.5% of which are sufficiently severe to require hospitalization; this was at least 25% lower than previous estimates a decade earlier. The estimated incidence for high-income countries is 0.015 episodes per child-year.[4]

The proportion of pneumonia cases obtained from efficacy estimates of vaccine trials was used to demonstrate the burden of pneumonia caused by *Streptococcus pneumoniae* and *Haemophilus influenzae* type b (Hib). Over 13 million new cases of pneumococcal pneumonia were estimated, with a global yearly incidence of 2228 cases per 100,000 children younger than 5 years of age, ranging from 462/100,000 cases in Europe to 3397/100,000 cases in Africa.[5] The case fatality rate ranged from 2% in the Western Pacific to 11% in Africa. The estimated global incidence of Hib pneumonia in the absence of vaccination was 1304 per 100,000 children younger than 5 years of age.[6]

A recent prospective study, including more than 2300 children in the United States, reported an overall incidence of radiologically confirmed CAP requiring hospitalization of 15.7 cases per 10,000 children and 62.2 cases per 10,000 among children younger than 2 years.[7] In South Africa, a birth cohort study following 697 infants during the first year of life has shown that the incidence of clinically defined pneumonia was 0.27 episodes per child-year, with 23% of those classified as severe pneumonia.[8]

Pneumonia can be caused by several different microorganisms, with viruses and bacteria being the most frequent agents. Viruses are, by far, the most prevalent cause of pneumonia throughout childhood, with the highest burden observed among infants. However, pathogens are epidemiologically interconnected, and coinfections, both with two or more viruses, or with viruses and bacteria, are very common. Coinfection rates up to 75% are commonly reported in infants.[7,8]

There are substantial age-related differences in the etiology of CAP during childhood (Table 25.1).[7] From birth to 28 days of life, most CAP is caused by group B streptococci, or Gram-negative enteric bacteria, although respiratory syncytial virus (RSV) also has a prominent role in this age group.[9] Beyond the neonatal period, RSV, influenza, and human metapneumovirus are among the most common viruses associated with a diagnosis of pneumonia.[7,9] *Chlamydia pneumoniae* and particularly *Mycoplasma pneumoniae* infections occur more often in school-age children and during adolescence, although there are many reports of these agents causing CAP in younger children as well.[7,10] In the first 6 months of life, *Chlamydia trachomatis,* a variety of respiratory viruses, *Bordetella pertussis* (see Chapter 32), or even *Ureaplasma urealyticum* may have a role (data are inconsistent).[11]

## Table 25.1

### Most Common Agents Causing Community-Acquired Pneumonia According to Age Group

| **AGE** | | | | |
|---|---|---|---|---|
| **Newborns** | **1–6 Months** | **6–12 Months** | **1–5 Years** | **Older Than 5 Years** |
| Group B Streptococcus<br>Enteric Gram-negative<br>RSV | Viruses<br>*Streptococcus pneumoniae*<br>*Haemophilus influenzae*<br>*Staphylococcus aureus*<br>*Moraxella catarrhalis*<br>*Chlamydia trachomatis*<br>*Ureaplasma urealyticum*<br>*Bordetella pertussis* | Viruses<br>*Streptococcus pneumoniae*<br>*Haemophilus influenza*<br>*S. aureus*<br>*Moraxella catarrhalis* | Viruses<br>*M. pneumoniae*<br>*S. pneumoniae*<br>*C. pneumoniae* | Viruses<br>*M. pneumoniae*<br>*S. pneumoniae*<br>*C. pneumoniae* |

The frequency rates for *S. pneumoniae,* the most prevalent bacteria causing CAP, are less affected by age. *S. pneumoniae* is a common pathogen throughout both infancy and childhood[7]; however, the incidence, severity, and complications from pneumococcal pneumonia have substantially reduced since the introduction of pneumococcal conjugate vaccine (PCV).[12–14]

Various pneumococcal serotypes have been associated with CAP, with specific and distinct prevalence rates in different parts of the world. The majority of the most important serotypes are included in PCV, especially the 13 valent pneumococcal vaccine (PCV13).[15,16]

Hib was a more frequent cause of CAP, before the widespread use of Hib immunization. It is still an important cause of CAP in countries where these vaccines are not universally available. Hib is more frequently observed in children younger than 5 years of age.[4] Nontypable *H. influenzae* may be more frequently associated with pneumonia than *S. pneumoniae* in immunocompetent and immunized children, as shown in studies from low- and middle-income countries.[17,18] Recently, several studies have reported on the impact of new conjugate vaccines (Hib and PCV) on pneumonia incidence, severity, and complications (see section "Prevention" of this chapter).[19,20]

As for other pathogens, pneumonia secondary to *Streptococcus pyogenes* is an infrequent cause of CAP nowadays; bacteremia or scarlet fever are more frequently diagnosed, especially among small children. Chickenpox (*Varicella zoster* virus) pneumonia may be associated with group A streptococcus since it seems to transiently affect host defenses and predispose to infection from commensal bacteria.[21,22]

*Staphylococcus aureus* pneumonia usually occurs secondary to inhalation of the pathogen. In rare cases, it can be the result of bacteremic spread, usually when there is a predisposing factor (e.g., a catheter, or use of intravenous [IV] drugs). *S. aureus* pneumonia tends to present as an acute, severe illness, especially because many first-line antibiotics commonly used to treat CAP do not provide appropriate coverage. Radiologic findings include bronchopneumonia with alveolar infiltrates, mostly unilateral. These infiltrates may coalesce and evolve to large areas of consolidation and cavitation. Destruction of bronchial walls may lead to air trapping and pneumatocele formation in at least 30% of cases. Pleural effusion and empyema are found in as many as 60% of the cases, and pneumothorax or pyopneumothorax are common complications. In the case of hematogenous spread of *S. aureus,* the radiologic picture is one of multiple bilateral pulmonary infiltrates that may cavitate. An increase in white blood cell counts is usual, but is not sufficiently sensitive or specific to suggest the etiologic diagnosis. Although the appearance of staphylococcal pneumatoceles may be dramatic, usually once the infection is controlled, the pneumatoceles resolve completely in the following few months.[23,24]

In recent years, community-associated methicillin-resistant *S. aureus* (CA-MRSA) has been increasingly recognized in otherwise healthy adults and children. CA-MRSA usually affects younger patients compared to hospital-acquired MRSA, and it is often susceptible to clindamycin, trimethoprim-sulfamethoxazole, and tetracyclines. Many strains of CA-MRSA carry the gene for Panton-

Valentine leukocidin, an exotoxin that is lethal to leukocytes, which causes tissue necrosis, skin lesions, necrotizing pneumonia, and necrotizing fasciitis.[25–27]

*Mycobacterium tuberculosis* should also be considered in the differential diagnosis of acute pneumonia, especially in high endemic areas (see Chapter 29). A recent systematic review reported 7.5% positive cultures in children with acute pneumonia, especially in endemic areas with a tuberculosis yearly incidence higher than 50 cases per 100,000 people.[28]

## Pathogenesis

The upper airways are commensally colonized by a variety of organisms, differently from the lower respiratory tract, which, until recently, was considered to be sterile. However, evolving knowledge of the human microbiome, using high-throughput sequencing-based studies, has shown that the lower airways are transiently or even chronically colonized.[29] Upper respiratory infections usually precede lower respiratory tract invasion by microorganisms, such as bacteria and viruses. Viruses usually reach the lower airways through contiguous spread and replication, and a similar mechanism of invasion is believed to occur with atypical bacteria. Microaspiration from the upper respiratory tract is the most common mechanism for most bacterial pneumonia. Macroaspiration, which is associated with an overwhelming inoculum, and hematogenous spread may also occur, with this latter mechanism more common in pneumonia caused by *S. aureus*.[30–32] In children, significant aspiration may occur due to swallowing dysfunction, gastroesophageal reflux, or congenital malformations.[33]

In the lower airways, the infectious process begins with an immune response leading to leukocyte infiltration, edema, and consequent small airway obstruction; this is followed by loss of tissue compliance, increase in airway resistance, atelectasis, abnormalities in ventilation-perfusion ratios, and necrosis. Virulence factors also facilitate the evasion of immune defenses, causing lung invasion and tissue destruction, such as occurs with the protein NS1 from some influenza strains, and with surface proteins of *S. pneumoniae.*[34–36] Impairment of the epiglottic and cough reflexes, interruption of mucociliary clearance by virus-induced changes in ciliary structure and function, and virus-induced enhancement of bacterial adherence are some of the mechanisms believed to contribute to this chain of events, which eventually leads to pneumonia. Evidence suggests that tumor necrosis factor-alpha (TNF-$\alpha$) and specific interleukins play a role in the exaggerated immune response observed in severe pneumonias.[37,38] Both humoral and cellular immune responses are crucial to protect children against pneumonia.[34,35,39]

# Clinical Features

## Symptoms

Children with pneumonia usually present with an acute illness, and some have no specific respiratory signs or symptoms. Common clinical findings include fever, chills, tachypnea, productive cough, lower chest indrawing, abdominal pain, and chest pain, all of which suggest—but do not prove—pneumonia. For Hib, the clinical picture is similar to other typical bacteria, although a more insidious onset is the rule.[40] A more gradual clinical onset associated with a combination of symptoms, such as headache, malaise, nonproductive cough, and low-grade fever/no fever, is generally associated with infection by atypical pathogens such as *M. pneumoniae.*[7,41]

Children can have fever and pneumonia without overt manifestations of respiratory disease. In a Canadian series of 570 pediatric patients with signs and symptoms suggestive of lower respiratory tract infection (LRTI), fever was the most sensitive sign, while grunting and retractions were the most specific, associated with alveolar infiltrates found on a chest radiograph.[42] A retrospective study from the United States showed that 5.3% of children with fever and no signs of LRTI, respiratory distress, or hypoxia may have a confirmed diagnosis of pneumonia by chest radiograph. The presence of a cough, as well as a longer duration of both a fever and a cough, was more likely associated with occult pneumonia. When a cough was absent, only 0.28% of the children had pneumonia.[43] The clinical presentation of pneumonia in the first months of life is generally different from that in older children. Infants in the first 3 months of life may present with a cough and respiratory distress associated with low-grade or no fever.[11]

## Physical Findings

The presence of age-specific tachypnea or lower chest indrawing is the main clinical sign used by the World Health Organization (WHO) for the diagnosis of pneumonia. According to the updated WHO guidelines, children with tachypnea or lower chest indrawing are classified as having pneumonia. Formerly, pneumonia in children with chest indrawing was classified as severe. However, evidence suggests that this last group is successfully treated with oral antibiotics. Children with danger signs (inability to drink, persistent vomiting, convulsions, lethargy, impaired level of consciousness, stridor, and severe malnutrition) are classified as having severe or very severe pneumonia.[2] The best way to assess the respiratory rate is over a 60-second period with the child alert and calm. Other respiratory signs may also indicate pneumonia, but no sign by itself can be used to diagnose or to rule out pneumonia. The respiratory rate seems to provide better interobserver agreement than auscultation of the chest, especially when examining infants.[44] Usually, the cut-off points are a respiratory rate of 60 breaths per minute in infants younger than 2 months of age, 50 breaths per minute for infants from 2 to 12 months of age, and 40 breaths per minute for children 1–5 years of age. Tachypnea is usually more sensitive and specific than crackles on auscultation, after the exclusion of a diagnosis of bronchiolitis or asthma. Tachypnea is highly sensitive for pneumonia, but is nonspecific; therefore it is widely used to diagnose CAP in low- and middle-income countries, where pneumonia is highly prevalent. By contrast, in affluent countries, most children (especially infants) who present acutely with an increased respiratory rate have either viral bronchiolitis or asthma associated with a viral infection. Systemic toxicity is less common in viral compared to bacterial infection because respiratory viruses rarely cause viremia.[45]

Wheezing is most frequently associated with infection by viral agents, and bacterial pneumonia, except for *Mycoplasma* or *Chlamydia,* is an unlikely cause.[46] In a case series of pneumonia from Wubbel and colleagues, pneumococcal infection was the most frequent diagnosis among patients without wheezing. On the other hand, viruses were the most frequent pathogens among those who wheezed.[46]

## Laboratory Tests

Higher white blood cell counts and concentrations of C-reactive protein, as well as procalcitonin, have been associated with bacterial pneumonia, but there is great overlap with pneumonia of viral etiology; therefore these tests are of little clinical utility for an individual subject.[47] Although consistent studies in children are scarce, evidence from adults suggest that inflammatory markers are useful for follow-up, especially to detect a possible treatment failure.[48]

## Radiologic Findings

In general, chest radiographs are standard practice in hospitalized children for whom a diagnosis of pneumonia is being considered. In the early clinical stages of disease, patients with bacterial pneumonia may have normal chest radiographs. There is also significant variation in the interpretation of these radiographs in children, with considerable intraobserver and interobserver disagreement. Specificity ranges from 42% to 100% in different studies because of the varying definitions of pneumonia.[49,50] Whether accuracy is improved by adding lateral chest radiographs is controversial, as studies have shown conflicting results.[51–53] WHO criteria for the standardization of chest radiograph interpretation defined primary end-point pneumonia as consolidation (“a dense opacity that may be a fluffy consolidation of a portion or whole of a lobe or of the entire lung, often containing air bronchograms”) or pleural effusion, and such an approach is reported to improve agreement. When comparing the presence of any infiltrate (end-point or other infiltrates not matching this definition), agreement was lower.[1]

A considerable proportion of children younger than 5 years of age with fever and leukocytosis, and without a well-defined source of infection, may have radiographic abnormalities consistent with pneumonia. In a study by Bachur and colleagues, 26% of the patients younger than 5 years of age who presented to the emergency department with fever, leukocytosis greater than 20,000 cells/mm$^3$, and no clinical findings suggestive of pneumonia, had a confirmed diagnosis of pneumonia on radiograph.[54] Therefore a plain chest radiograph is part of the investigation of nonspecific clinical signs of infection in this age group.

Because chest radiographs do not change the outcome of LRTIs, guidelines do not recommend them for children older than 2 months of age who are cared for in an outpatient setting.[42,45,55]

Although alveolar or lobar pneumonia (Fig. 25.1) is more frequently observed in infection from typical bacteria, when compared with interstitial pneumonia (which occurs more frequently in viral pneumonia or with *Mycoplasma* or *Chlamydia* infection), it is usually impossible to make an etiologic diagnosis based on a chest radiograph.[44] No follow-up radiographs are needed to evaluate a CAP with good clinical response, except for cases of round pneumonias, lobar collapse, or whenever clinical deterioration may occur.[45]

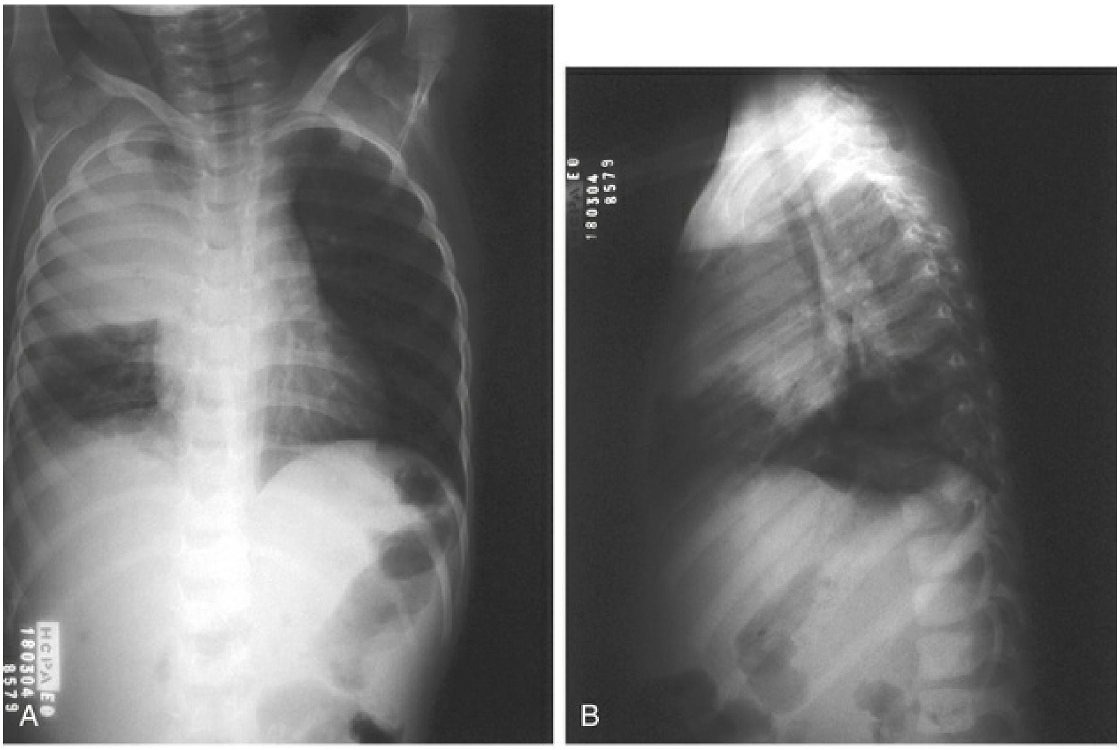

**FIG. 25.1** Pneumococcal pneumonia. Positive blood cultures for *Streptococcus pneumoniae.* Dense consolidation of right upper and middle lobes with air bronchogram. (A) Anteroposterior view. (B) Lateral view.

Recent reports have shown that bedside lung ultrasound (US) may be an option for the diagnosis of pneumonia in children.[56] The accuracy is similar or higher than chest radiographs, with the possibility of bedside use and avoidance of radiation exposure.[57] However, this technique requires specialized training, and further studies are needed.[58]

Computed tomography (CT) scans should not be used routinely unless another underlying diagnosis is suspected (e.g., a tumor or abscess) because of radiation concerns, and because less invasive imaging techniques usually suffice for diagnosis and management.[59] A possible exception would be in cases where a surgical approach is being considered.[60]

Some studies have also compared lung magnetic resonance imaging (MRI) to conventional chest radiography. High agreement was reported, with greater sensitivity of MRI for complications, such as lung abscess and necrosis, with the advantage of it being a radiation-free procedure. However, the role of MRI is yet to be determined, since accuracy is not clearly superior, and it is not readily available in most settings; also, it requires sedation or a cooperative patient, and is more expensive than traditional methods.[61,62]

# Etiologic Diagnosis

Confirmation of pneumonia etiology may be difficult. Various approaches have been used to try to address this issue. Diagnostic methods for etiologic identification can be divided into microbiologic, immunologic, and molecular methods of detection (see Chapter 22). The gold standard for etiologic diagnosis in CAP is either by collecting direct lung specimens or by performing a bronchoalveolar lavage (BAL), but these methods are unacceptable for routine clinical purposes. BAL in children is helpful in nonresponding patients with severe infections, and for nosocomial or life-threatening infections. Blood cultures are positive in less than 10% of the samples and should be considered only in hospitalized children or those with complicated pneumonia. Repeating blood cultures to document resolution of bacteremia is not recommended for patients who are clinically improving, except for those with *S. aureus* pneumonia.[27,45]

A sputum examination is a viable alternative for respiratory sampling. It is practical for adolescents and school-aged children and can be induced in young children, but it should be interpreted with caution because upper airway commensals, which can be pathogenic in the lower airways, are usually contaminants. Bacterial cultures of the throat or nasopharynx do not correlate well with lung parenchyma and are more likely to confound than to help, with the known exception of the high correlation between upper and lower airway cultures in sick patients with cystic fibrosis.[27]

Pleural fluid cultures may grow potential pathogens, but the usual practice of empiric antibiotic use in the early phases of pneumonia decreases the sensitivity of this method. However, pleural fluid should be cultured whenever technically accessible, unless the effusion is too small or when clinical recovery is uneventful.[27]

## Antigen and Serologic Tests

Detection of bacterial antigens in urine or plasma has been used, but results are conflicting, and sensitivity and specificity are low. In children, pneumococcal urinary antigen has a high sensitivity, but a positive test is frequently due to nasal carriage.[27,45]

For respiratory viruses, tests based on antigen detection are more often available and, in general, have greater specificity than sensitivity. Rapid immunoassay tests for influenza and RSV have a sensitivity of 66% and 80% and a specificity of 98% and 97%, respectively.[63,64] Despite specificity values greater than 94% for viruses overall, direct immunofluorescence assays do not reach sensitivity levels above 75% for most viruses, with the exception of RSV, which is around 90%.[65,66]

Serology is useful for some agents such as *M. pneumoniae, C. pneumoniae,* and *S. pneumoniae;* paired acute and convalescent titers are the gold standard, with the caveat of the diagnosis having only retrospective value in most situations.[67] For *M. pneumoniae,* detection of immunoglobulin (Ig)M antibodies in acute disease is usually less than 80%.[68,69]

## Polymerase Chain Reaction

Respiratory secretions, pleural effusion, lung aspirate samples, or blood, are sources for specimen testing. Molecular biology techniques have uniformly high sensitivity and specificity in diagnosing viral infections, apart from agents whose pathogenicity is still not well established, such as human bocavirus (which remains polymerase chain reaction [PCR] positive for months after acute infection).[45,70] PCR is a good diagnostic tool in research and can be used by clinicians in special situations, but it does not differentiate carrier state from disease. Quantitative PCR may solve these problems if cut-off levels for disease and carrier state can be adequately defined.

# Diagnosis and Differential Diagnosis

Pneumonia should be suspected in children with fever, cough, tachypnea, lower chest indrawing, or crackles on chest auscultation. However, no single clinical feature has sufficient accuracy to diagnose pneumonia. Abdominal pain or nausea, when associated with fever, can present as the sole clinical finding in pneumonia affecting the lower pulmonary lobes.[45,71]

The differential diagnosis of CAP includes viral bronchiolitis, asthma, cardiogenic causes of tachypnea, interstitial lung diseases, and chemical pneumonitis, especially those secondary to aspiration syndromes. Infants and small children presenting with fever and respiratory signs are frequently sent for a chest radiograph and often receive antimicrobial treatment for a presumptive diagnosis of bacterial pneumonia. Importantly, a chest x-ray cannot reliably differentiate between viral and bacterial etiologies, which may coexist.[72] Radiologic signs of bilateral interstitial lung infiltrates or atelectasis, signs of bronchitis (true wheeze on auscultation), and generalized hyperinflation, though not definitive markers, are very likely to indicate viral pneumonia (Fig. 25.2).

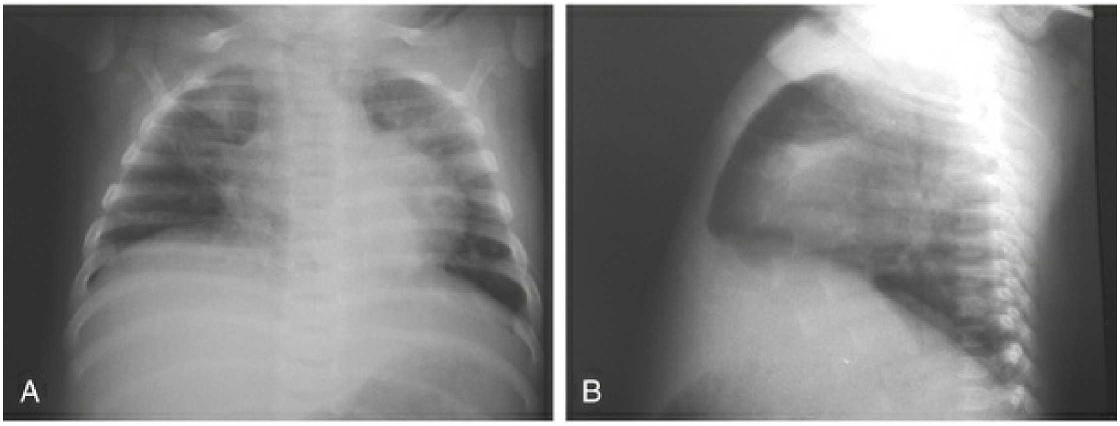

**FIG. 25.2** Viral pneumonia in a 6-month-old infant with respiratory-syncytial-virus–positive nasopharyngeal aspirate. (A) Anteroposterior radiograph with bilateral interstitial infiltrates and patchy atelectasis. (B) Lateral radiograph with hyperinflated lungs; increased anteroposterior diameter, flattening of the diaphragm, and mediastinal air cushion.

Although “atypical” pneumonia is often described with several different presentations, in clinical practice neither signs nor symptoms alone, or with radiologic findings have sufficient accuracy to differentiate *M. pneumoniae* infections from other agents.[68,73] Tuberculosis should always be considered as a possible diagnosis, especially among children living in, or in families that have recently moved from, endemic areas. Nonresolving pneumonia with persistence or recurrent radiologic findings should alert the physician to possible noninfectious primary causes or infection with bacterial agents, such as *M. tuberculosis*.[74] Another important differential diagnosis is that of round pneumonia, since these and infected congenital malformations or thoracic masses may have similar radiologic presentations (Fig. 25.3).

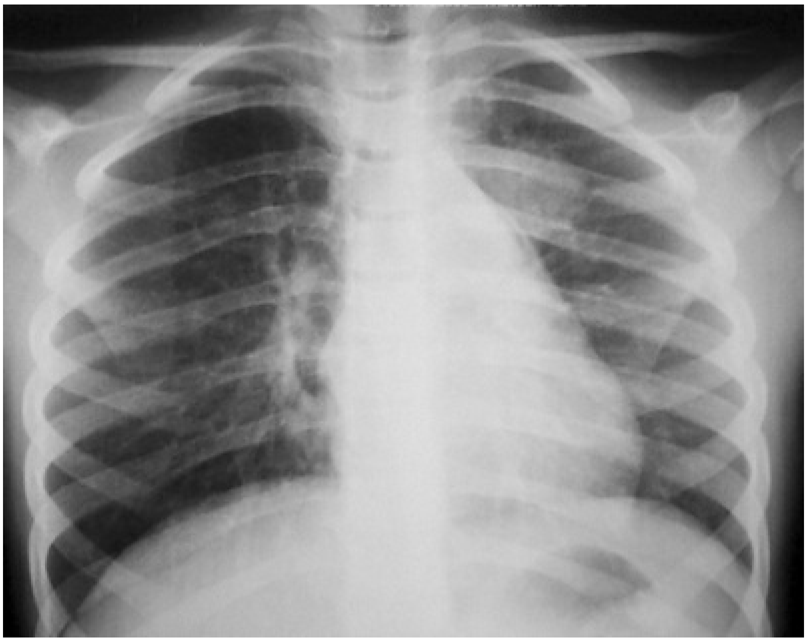

**FIG. 25.3** Round pneumonia. Opacity in the left upper segment, partially concealed by the mediastinal shadow.

## General Management

Infants and children with CAP without danger signs can be safely cared for at home. In this situation, the child usually should be reexamined within 48 hours after beginning treatment. According to the most current guidelines, for infants aged less than 2 months, $SaO_2$ of 90%–92% or less, cyanosis, a respiratory rate greater than 70 breaths per minute, difficulty breathing, intermittent apnea, grunting, an inability to feed, failure after oral therapy, severe malnutrition, or a family incapable of providing appropriate care, are all indications for hospital admission.[2,27,45,75,76] In older children, the indicators are a $SaO_2$ of 92% or less, cyanosis, respiratory rate greater than 50 breaths per minute, grunting, difficulty breathing, signs of dehydration, or a family incapable of providing appropriate observation or supervision.[45]

General management for hospitalized children includes oxygen delivery through a mask or nasal cannula to keep oxygen saturation above 92%, antipyretics, and IV fluids if the child is unable to drink. Fluid intake should be carefully monitored because pneumonia can be complicated by hyponatremia secondary to the syndrome of inappropriate antidiuretic hormone secretion. The benefit of nasogastric tube feeding should be weighed against its potential for respiratory distress due to the obstruction of a nostril, or by inducing gastroesophageal reflux.

Supplemental oxygen should be given when oxygen saturation is 92% or lower.[45,76] In most mild cases, this can easily be administered via a nasal cannula, a head box, or a facemask.

No randomized, controlled trials have addressed the use of noninvasive ventilation for children with pneumonia. Respiratory failure, when present, should be managed appropriately and noninvasive ventilation may be used to avoid tracheal intubation. Children should be admitted to an intensive care facility with continuous cardiorespiratory monitoring capabilities when invasive ventilation is required, or pulse oximetry measurements are below 92% with the child on inspired oxygen concentrations of 50% or more.[27,45]

There is no evidence for the usefulness of chest physiotherapy in the management of CAP; therefore it is not currently indicated.[45,77]

## Treatment With Antimicrobials

Since viruses are the main cause for many cases of CAP in childhood, it is appropriate to be cautious and not overtreat these rather common situations with antibiotics. However, therapeutic decisions can be difficult because most tests do not adequately differentiate viral from bacterial infection in an individual child. An additional issue is the fact that many patients harbor mixed viral and bacterial agents.[46]

The problem of bacterial resistance to antibiotics has increased steadily in the last few years, so antibiotics should be used judiciously and narrow-spectrum agents used whenever appropriate. Prior antibiotic therapy, daycare attendance, travel, and coexisting morbidities are risk factors for resistance. It is also important to keep in mind that, in an era of effective vaccines against Hib and *S. pneumoniae,* previous antibiotic regimens may have to be reevaluated.[78]

Antibiotics should be started whenever bacterial pneumonia is the most probable diagnosis.[79] Since a definitive etiologic diagnosis is more the exception than the rule, usually antibiotics are started on an empirical basis. The local prevalence of CAP-causing agents should be considered.

Several randomized studies assessing different antibiotics for pneumonia have shown that children under 5 years with tachypnea or indrawing of the lower chest without danger signs can be safely treated with oral amoxicillin.[79,80] Co-trimoxazole is no longer recommended, since it is less effective than amoxicillin. Furthermore, higher doses of amoxicillin, that is, 80–90 mg/kg per day in two doses, are more effective than a lower dose and are now recommended.[2,79]

Some studies have recently reviewed the issue of treatment duration. A multicenter study from Pakistan, which enrolled 2188 children between the ages of 2 and 59 months, showed the equivalence of a 3-day or 5-day course of amoxicillin in the treatment of nonsevere pneumonia, as diagnosed by the WHO criteria. Of note were a low prevalence of positive radiographic findings (14%) and a relatively high rate (20%) of treatment failure, which suggests that there may have been a high proportion of viral pneumonia.[81]

For severe pneumonia or very severe pneumonia, according to the WHO classification, there is no evidence supporting a shortened course, and patients should be treated with IV antibiotics.[2,82] Interestingly, although not yet universally adopted as the standard of care, there is growing evidence from both adult and pediatric studies that the use of procalcitonin as a biomarker for bacterial infection allows for the reduction of antibiotic duration, without any increase in adverse outcomes in bacterial pneumonia.[83,84]

## Choice of Antibiotics

The choice of antibiotics is based on clinical features, prevalence data for different organisms in different age groups, and regional variations in pathogens. All current guidelines recommend oral amoxicillin as the first choice, and penicillin or ampicillin if IV treatment is required.[2,27,45,75,76]

Penicillins (either intramuscular [IM], IV, or orally) can be used for most pneumococcal pneumonias, unless highly resistant strains are identified. The prevalence of penicillin resistance also varies widely throughout different countries and continents.[85,86] The degree of penicillin resistance does not appear to cause adverse outcomes for hospitalized patients with a diagnosis of pneumococcal CAP, since high parenteral penicillin serum concentrations are obtained with usual dosage regimens, which are much higher than the observed levels of resistance for these bacteria.[87] Hospitalized patients with pneumococcal pneumonia caused by strains with minimum inhibitory concentration (MIC) up to 2 μg/mL respond well to adequate doses of β-lactam antibiotics (e.g., 200,000–250,000 U/kg per day of penicillin). Susceptibility breakpoints have been revised due to the cumulative evidence of clinical improvement even with conventional doses of penicillin for strains that were previously considered intermediately resistant. Consequently, current breakpoints of resistant *S. pneumoniae* for parenteral penicillin in the case of nonmeningeal infections are ≤2 μg/mL (susceptible), 4 μg/mL (intermediate), and ≥8 μg/mL (resistant). However, for oral penicillin, the previous breakpoints are still valid, due to lower serum levels achieved with enteral presentations.[27,87] High doses of oral penicillin, ampicillin, and amoxicillin have been recommended whenever intermediately susceptible pneumococcus strains are considered. As mentioned above, the WHO recommends oral amoxicillin in higher doses twice daily as the first-line treatment for pneumonia.

Vancomycin or teicoplanin should be reserved for severely ill patients, when coverage for highly resistant pneumococcus is desired, because overuse may lead to increased resistance from other pathogens. Antibiotic resistance is usually associated with changes in the penicillin-binding sites of the transpeptidases of the bacteria, and it may be associated with cross-resistance to other β-lactams and carbapenems. Worldwide, most resistant pneumococcus strains were from serogroups 23F, 6A, 6B, 9V, 19A, 19F, and 14; five of these are covered by the heptavalent PCV7, and all are included in the PCV13.[88]

Resistance to macrolides is associated with the alteration of the 50S ribosomal binding site, preventing the drug from inhibiting protein synthesis, or the presence of efflux pumps to macrolides. Overall macrolide resistance is around 30%.[89]

When a causative agent is known, narrow-spectrum antibiotics are preferred. Table 25.2 shows appropriate antibiotic choices, based on bacteriologic tests and MICs.

## Table 25.2

**Choice of Antibiotic Treatment for Community-Acquired Pneumonia When Typical Bacteria Are Identified**

| **Pathogen** | **First Choice** | **Other** |
|---|---|---|
| *Streptococcus pneumoniae,* penicillin susceptible or intermediate | Penicillin, ampicillin, or high-dose amoxicillin | Cefuroxime, ceftriaxone, azithromycin |
| *S. pneumoniae,* penicillin resistant (MIC ≥ 4 μg/mL) | Second- or third-generation cephalosporins for sensitive strains; vancomycin | |
| *Staphylococcus aureus* | Methicillin/oxacillin | Vancomycin or teicoplanin (for MRSA) |
| *Haemophilus influenzae* | Amoxicillin | Amoxicillin/clavulanate, cefuroxime, ceftriaxone, other second- and third-generation cephalosporins |
| *Moraxella catarrhalis* | Amoxicillin/clavulanate | Cefuroxime |

*MIC*, Minimum inhibitory concentration; *MRSA*, methicillin-resistant *S. aureus.*

In real-life situations, causative agents are rarely identified, and the choice of antibiotics is based on models that include both the age of the child and the clinical presentation.

Neonates with CAP can be treated with a combination, such as IV ampicillin and gentamicin. Methicillin/oxacillin may be the best choice if the clinical picture is suggestive of *S. aureus* infection. For symptomatic children between 3 weeks and 3 months of age with interstitial infiltrates visible on chest radiograph, if a viral etiology is not the most likely diagnosis, a macrolide should be used to cover for agents such as *C. trachomatis, B. pertussis,* and *U. urealyticum.* Children between 4 months and 5 years of age with CAP are most likely infected by pneumococcus, viral agents, or both, and amoxicillin, penicillin, or ampicillin are the drugs of choice (see Tables 25.1 and 25.2). Some experts suggest macrolides (e.g., azithromycin, clarithromycin, or erythromycin) as optional choices because they cover both typical and atypical bacteria. Of note, azithromycin has a distinct pharmacokinetic profile and it does not reach high serum levels, which is a potential disadvantage in the treatment of bacterial pneumonia.[90] Pneumococci have become increasingly macrolide resistant, indicating that macrolides should be reserved as second-line treatment or for situations in which atypical infections are either probable or confirmed by laboratory tests.[89]

Infants and young children with CAP can receive ampicillin, amoxicillin, penicillin, or even a third-generation cephalosporin orally, unless there is vomiting, or when the patient is so sick that hospitalization and parenteral antibiotics are needed. In a recent Cochrane review, three controlled trials comparing oral with parenteral antibiotics in severe pneumonia, according to the WHO criteria, were evaluated and there were no differences in outcomes between oral and parenteral antibiotics.[91] Since children with serious signs and symptoms (e.g., inability to drink, cyanosis, and convulsions) were not included, no definitive conclusions can be drawn from the review for this specific group of patients.[91] In regions of the world where Hib immunization is not available, clinicians should consider amoxicillin/clavulanate, cefprozil, cefdinir, cefpodoxime proxetil, cefuroxime, or ceftriaxone as drugs of choice. The addition of a β-lactamase inhibitor does not confer additional coverage for pneumococcus because this is not its resistance-associated mechanism.

Whenever there is a positive culture or a clinical picture suggestive of *S. aureus,* specific antibiotic coverage against this pathogen should be added (e.g., methicillin, oxacillin, clindamycin, or vancomycin in the case of MRSA strains).

The diagnosis of CA-MRSA should be considered in cases presenting with necrotizing pneumonia. Atypical bacteria causing

CAP are not common in infancy and early childhood, and should be considered only in deteriorating cases. Recent data on the use of ceftaroline (a fifth-generation cephalosporin with anti-MRSA activity) in children suggest that it is effective against CA-MRSA pneumonia. Nonetheless, specific epidemiologic or treatment data on MRSA pneumonia in children are still very scarce.[92] If the clinical and radiologic findings suggest the possibility of an atypical agent, then a macrolide is the first choice, and a β-lactam should be added in cases of poor response.[27]

Both cefuroxime and cefixime should be considered as good options whenever cost is not a main issue. If atypical pneumonia is suspected, a macrolide or azalide (e.g., azithromycin) should be used for 5–7 days. The role of azithromycin, clarithromycin, and erythromycin is limited to extending the antimicrobial spectrum to atypical organisms, because these agents are relatively inactive against *H. influenzae,* and there is increasing resistance among *S. pneumoniae.* Thus, such choices should be tailored to treat organisms that do not respond to first-line therapy.[93] Pneumonia in HIV-infected children may present with a broader spectrum of pathogens, requiring a specific pattern of antibiotic cover (see Chapter 66).

Table 25.3 and Box 25.1 summarize these recommendations, including suggested drug regimens.

## Table 25.3

**Choice of Antibiotic Treatment for Community-Acquired Pneumonia According to Age and Clinical Picture**

| Age/Clinical Picture | Inpatient | Outpatient |
|---|---|---|
| Newborn | Ampicillin + gentamicin | — |
| 1 month to 5 years | Penicillin or ampicillin[a] | Amoxicillin[a] |
| 5 years and older: alveolar infiltrate, pleural effusion, toxic appearance | Penicillin or ampicillin; add macrolide if not responding | — |
| 5 years and older: interstitial infiltrate | Macrolides; consider adding a β-lactam if not responding | Macrolide |
| Necrotizing pneumonia | Oxacillin/nafcillin; vancomycin. Consider adding third-generation cephalosporin | |

[a] Macrolides if atypical pneumonia suspected.

**Box 25.1**

### Suggested Antibiotic Dosages for the Treatment of Community-Acquired Pneumonia

Penicillin 200,000 U/kg per day IV q4h or q6h (if resistant strains are to be covered, up to 400,000 U/kg per day, for 7–10 days)
Ampicillin 50 mg/kg per day PO q6h, for 7–10 days and 100–200 mg/kg per day IV q6h for 7–10 days
Amoxicillin 80–90 mg/kg per day PO q12h, for 5 days (if resistant strains are to be covered, dose can be increased up to 100 mg/kg per day)
Amoxicillin/clavulanate 40 mg/kg per day PO of amoxicillin for 5 days
Oxacillin/nafcillin 150 mg/kg per day IV q6h, maximum 12 g/day, for 14–21 days
Cefuroxime 30 mg/kg per day PO q12h, for 5–7 days and 150 mg/kg per day IV q8h, for 7–10 days
Ceftriaxone 50–75 mg/kg per day IM/IV qd, for 7–10 days
Cefotaxime 200 mg/kg per day IV q8h, for 7–10 days
Cefprozil 15–30 mg/kg per day PO q12h, maximum 1 g/day, for 7–10 days
Cefdinir 14 mg/kg per day PO q12h, for 7–10 days
Cefpodoxime proxetil 10 mg/kg per day PO q12h, maximum 400 mg/day, for 7–10 days
Azithromycin 10 mg/kg per day PO qd, for 3–5 days
Clarithromycin 15 mg/kg per day PO q12h, maximum 1 g/day, for 5–7 days
Erythromycin 40 mg/kg per day PO q6h, for 5–7 days
Vancomycin 40–60 mg/kg per day IV q6h, for 7–10 days (14–21 days for *Staphylococcus aureus*)
Gentamicin 7.5 mg/kg per day IM/IV q8h, for 7–10 days

## Slowly Resolving Pneumonia

This term refers to the persistence of either clinical or radiologic findings of pneumonia beyond the normal time course during which one would expect the infection to resolve (i.e., between 48 and 96 hours after empiric "adequate" antimicrobial treatment). However, radiologic resolution may take several weeks. Radiologic abnormalities are found 3–7 weeks after initial episode in a substantial proportion of patients.[94] One example of slowly resolving pneumonia is when patients fail to respond to conventional treatment, and another is when clinical symptoms or radiologic signs persist, even in the presence of clinical improvement. During this period, it is not recommended that antimicrobials be changed unless there is clear evidence that other microorganisms, not covered by the initial empiric choice of therapy, are involved (e.g., *S. aureus* with developing pleural effusion or in the presence of pneumatoceles, when initial therapy was amoxicillin). The presence of empyema or an underlying lung abscess should be considered whenever there is persistence of fever with or without pleuritic pain (basal segment pneumonias may mimic acute abdominal pain). These situations often require additional interventions, rather than a change in antibiotic regimen (Fig. 25.4).

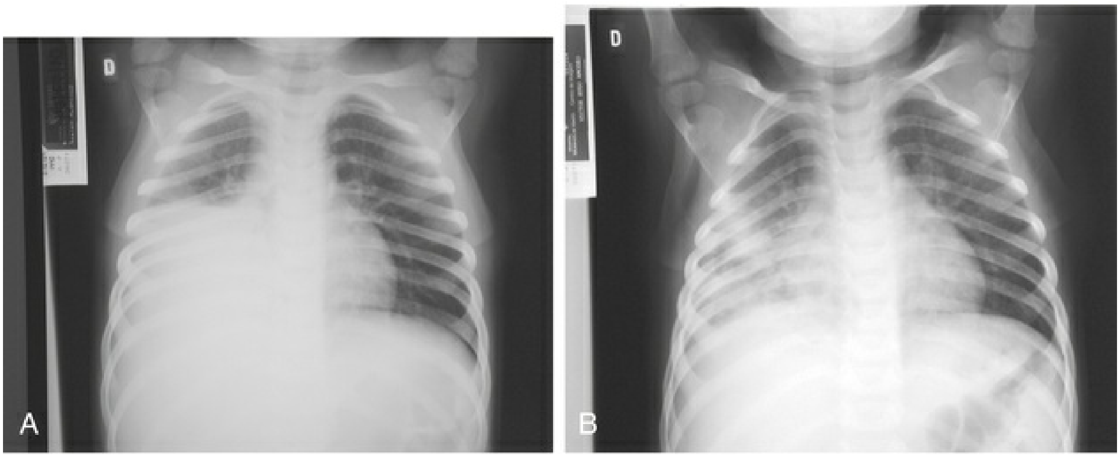

**FIG. 25.4** Slowly resolving pneumonia. (A) A 3-year-old child with presumptive diagnosis of pneumococcal pneumonia. Lower and middle lobe consolidation is shown; treatment started with intravenous benzyl penicillin. This evolved into a pleural effusion, which later necessitated a thoracotomy. (B) The same child 3 weeks after the first diagnosis; the child was in a good

clinical condition on discharge. Aeration of previously consolidated areas.

Factors such as an inappropriate choice of drugs, unexpectedly resistant microorganisms, inadequate dosage, complications, or poor compliance of oral therapy can result in slowly resolving CAP and should always be considered. Antibiotic failure may be the case in either slow or unresponsive pneumonia. The inappropriate choice of antibiotics may be an issue; for example, when there is inadequate coverage for atypical organisms. In endemic areas, tuberculosis should always be considered because its radiologic appearance may mimic bacterial pneumonia.

Inadequate host defenses or other coexisting diseases (e.g., ciliary dyskinesia, cystic fibrosis, HIV, or noninfectious causes) may also be associated with slowly responding or nonresponsive pneumonia. Several differential diagnostic tests for such possible comorbidities may be considered, including bronchoscopy with BAL, chest CT scan, or lung biopsy. Blood, pleural, and sputum cultures, as well as PCR, should be considered for the diagnosis of possible atypical microorganisms.

Other conditions, such as persistent alveolar collapse or atelectasis, may be secondary to obstruction of the bronchial lumen, from either foreign body aspiration or lymph node enlargement. Congenital malformations, such as pulmonary sequestration, bronchogenic cysts, or other mediastinal masses, also may be causes for delayed radiologic improvement, especially if the appearance resembles round pneumonia. It is important to ensure adequate follow-up of all children with CAP who do not have a typical course with full resolution of their symptoms and signs.[27,45,95]

# Major Clinical Complications

## Necrotizing Pneumonia

Necrotizing pneumonia is characterized by necrosis and liquefaction of consolidated lung tissue, which may be complicated by solitary, multiple, or multiloculated radiolucent foci, bronchopleural fistulas, and intrapulmonary abscesses. Most cases are confined to a single lobe, but sometimes there is multilobar involvement. Pneumatoceles are commonly associated with and develop after localized bronchiolar and alveolar necrosis, which allows for the one-way passage of air into the peripheral airways and alveoli. Necrotizing pneumonia is usually secondary to pneumococcus, *S. aureus*, or, less commonly, *Pseudomonas aeruginosa* infections. CA-MRSA is often associated with this clinical presentation, since there is production of Panton-Valentine leukocidin, an exotoxin that causes tissue necrosis. In Europe, methicillin-sensitive *S. aureus* (MSSA), producing this same exotoxin, has been associated with necrotizing pneumonia.[25,96,97]

## Pleural Effusion and Empyema

Pleural effusion occurs when an inflammatory response to pneumonia causes an increase in permeability of the pleura with an accumulation of fluid in the pleural space. There is increased capillary permeability after parenchymal lung injury, favoring the migration of inflammatory cells (neutrophils, lymphocytes, and eosinophils) into the pleural space. When bacteria enter the pleural space, pus appears, characterizing empyema. Empyema may also be secondary to bronchiectasis and lung abscess.[98,99]

Either the child presents with typical, but usually more severe, signs of pneumonia or, after a few days of usual pneumonia symptoms, children deteriorate clinically, with persistent fever or respiratory distress. Pleuritic pain is common. In cases where infection is in the lower lobes, abdominal pain is often present. On physical examination, there is reduced air entry and dullness to percussion over the affected area.[98] Radiographic findings may progress to complete hemithorax opacification with mediastinal contralateral deviation (Fig. 25.5). Unlike adults, where mortality rates around 40% are expected, the typical clinical outcome of children is good with full recovery. Bronchopleural fistula, lung abscess, and perforation through the chest wall *(empyema necessitatis)* are uncommon complications in children.[60]

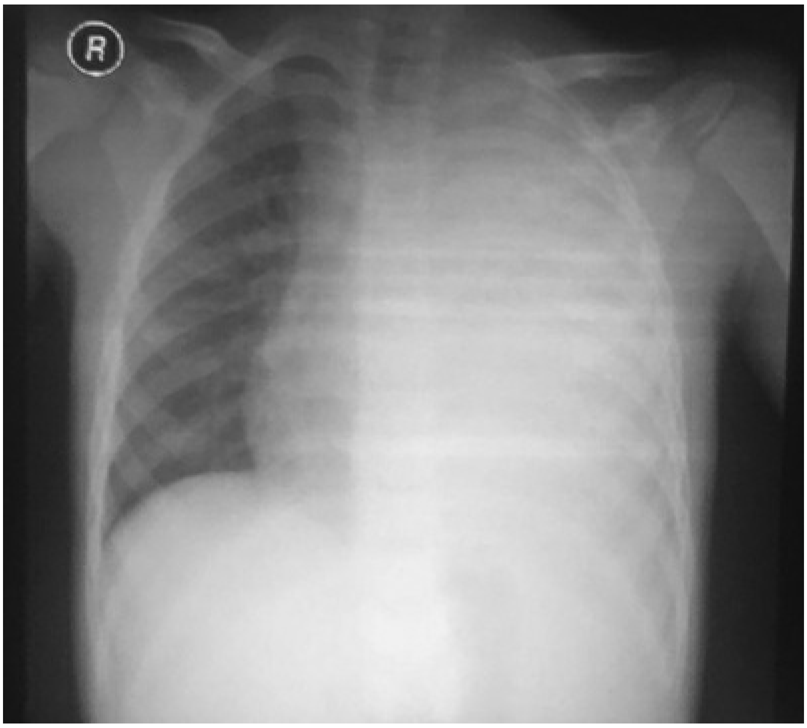

**FIG. 25.5** Empyema with complete hemithorax opacity and mediastinal deviation to the contralateral side.

After the introduction of PCV7, a rise in empyema incidence was reported in some settings.[100–103] However, a reduction after PCV13 introduction was detected, probably due to better coverage of serotypes related to complications, such as serotype 1.[14,104,105]

Blood culture is recommended to identify the causative organism, but positive cultures in patients with empyema occur only in 10%–22% in most series. Acute phase reactants are not helpful in detecting parapneumonic effusions or differentiating them from empyema. Other biochemical tests from the pleural fluid are usually inadequate to identify the causal agent or to differentiate empyema from an uncomplicated parapneumonic effusion.[60,98]

Chest radiographs should always be obtained when there are signs indicating an inadequate clinical course. Obliteration of the costophrenic angle and a rim of fluid may be seen ascending the lateral chest wall (meniscus sign) on posterior-anterior or anterior-posterior radiographs. If the film is taken when a child is supine, the appearance can be of a homogeneous increase in opacity over the whole lung field. A complete whiteout of a hemithorax may be seen with a large pleural effusion. Another radiographic finding of empyema is that of scoliosis, concave to the side of the collection, reflecting that the child may be choosing a protective position to avoid pain.

Loculation, defined as fluid not moving freely due to pleural fibrinous adhesions, can be diagnosed by evaluating the chest dynamically (i.e., in different positions) by means of plain radiographic films or by US. Statically, loculation can probably be inferred when a collection adopts a lenticular shape with internal convexity, while a freely moving collection should form an internally concave meniscus paralleling the chest wall.[99] Although chest radiographs are helpful in diagnosing pleural effusions, they are not useful for clinical follow-up because full radiologic recovery may be slow, and findings may not be clinically significant. Chest radiographs will normalize in two-thirds of the children 3 months after the acute event; 90% should have normal radiographs by 6 months, and all should be normal by 18 months.[106]

US is very useful to differentiate between solid and liquid content in the chest, and to mark the best spot for tube insertion in the case of empyema. It is particularly valuable in the case of whiteout of a lung, where atelectasis, consolidation, and effusion should be differentiated. Either US or CT scans are advocated to identify fibrin deposition, but fibrinous septations are better visualized using US. US can estimate the size of the effusion, can differentiate free from loculated pleural fluid, and can determine the echogenicity of the fluid. It can be used to guide chest drain insertion or thoracentesis with the radiologist or radiographer marking the optimum site for drainage on the skin. In most cases, plain radiographs or US can distinguish an abscess from a septated pleural effusion, although sometimes a CT is needed. US is considered essential in the management of children with parapneumonic effusions. Guidelines from the British Thoracic Society recommend the referral of such patients if the health care facility does not have these diagnostic options available.[60]

Pleural fluid should always be sent for Gram stain, microbiological testing, and, wherever possible, for PCR diagnosis. Culture and PCR (Xpert) for *M. tuberculosis* should also be done in tuberculosis (TB) endemic areas. A cell count should be considered, and when lymphocytosis is prominent, tuberculosis or malignancies are more likely. In parapneumonic effusions, one should expect a predominance of neutrophils. Low glucose, low pH, and high lactate dehydrogenase (LDH) in adults have long been used to predict empyema development, but in children their role to guide management remains undetermined. Although it is probable that biochemical characteristics from parapneumonic effusions in children are not that different from those in adults, such tests do not change the management nor the outcome.[27,60]

All children with parapneumonic effusion and empyema should be admitted to a hospital. Children who need drainage of the effusion should preferably be managed at a tertiary center under the supervision of a specialist. Different outcomes have been used to compare the efficacy of different treatment strategies (e.g., length of hospitalization, radiologic resolution, or pulmonary function tests) because mortality rates are very low. Smaller effusions less than 10 mm thick can usually be managed with antibiotics alone, and these should especially cover *S. pneumoniae; S. aureus* should be considered when pneumatoceles are present and the child is toxic. Although not based on specific randomized trials, a panel of experts from the British Thoracic Society recommends one of the following: cefuroxime, co-amixiclav, penicillin plus flucloxacillin, amoxicillin plus flucloxacillin or clidamycin when effusion follows CAP. Broader coverage should be the choice in cases of hospital-acquired pneumonia and following surgery, trauma, or aspiration. The same panel recommends continuation of antibiotics for 1–4 weeks after discharge or even longer when there is residual disease.[60]

Antibiotics alone should not be the main strategy for managing effusions that are enlarging, or those that are big enough to cause respiratory distress. Therapeutic options besides antibiotics are thoracentesis, chest drain insertion with or without the instillation of fibrinolytic agents, and surgical techniques, such as video-assisted thoracoscopic surgery (VATS), minithoracotomy, and standard thoracotomy with decortication. Few studies have compared repeated thoracentesis versus catheter drainage. In prospective, uncontrolled studies, where chest drain alone (i.e., without further surgical intervention) was used, the length of hospital stays varied between 14 and 24 days, and all children fully recovered.[107]

After chest tube placement, a chest radiograph should be obtained to check the tube position and to ensure there is no pneumothorax. Even though drainage with tube thoracotomy and antibiotics may be all that is needed for the exudative stage, the presence of loculation and fibrinous adhesions may limit the success of this therapy. The objectives of treatment of stage 2 empyema (fibrinopurulent), apart from antibiotics, are fluid removal and debridement of the fibrinous layer of the pleura to allow the lung to expand. In these situations, fibrinolytic drugs are used to lyse the fibrinous strands in loculated empyemas, thereby clearing lymphatic pores, which restores pleural fluid circulation. Different fibrinolytics (e.g., streptokinase, urokinase, and alteplase) have been studied in randomized, clinical trials comparing them to saline or to VATS, and the results were variable. The success rate of fibrinolytics is 80%–90% in case series, with pain being the major side effect. Bleeding diathesis and pneumothorax are contraindications to fibrinolytics. Other possible side effects are fever and, less commonly, bleeding and allergic reactions.[60,107]

The American Pediatric Surgical Association recommends fibrinolytics as the first choice of treatment for empyema that requires drainage, particularly when it is associated with loculations, since fibrinolytic therapy can shorten the duration of treatment and length of hospital stay. On the other hand, systematic reviews have not shown outcome differences when comparing fibrinolytics to VATS. There was no evidence of a clinically significant difference in the length of stay between VATS and chest drain with fibrinolytics, except in one of the trials; insertion of a small-bore chest drain used with fibrinolytics was associated with lower hospital costs.[108–112] It should be emphasized that children virtually always recover irrespective of the treatment they receive, and that the long-term outcome is not affected.[98,107]

While sequelae occur in many adults, full recovery is the rule in children, although a temporary restrictive pattern can be seen in pulmonary function tests soon after hospital discharge.[27,60]

## Lung Abscess

Another possible complication of pneumonia is a lung abscess. A pulmonary abscess is a thick-walled cavity that contains purulent liquid. The pathogenesis of a lung abscess begins with inflammation of the parenchyma, which progresses to necrosis, cavitation, and abscess formation. The abscess may be secondary to predisposing conditions (e.g., pulmonary aspiration), especially in children with neurodevelopmental delay, congenital malformations, immunodeficiency, or endocarditis. In the case of pulmonary aspiration, this may be associated with either large or frequently aspirated small volumes. Usually, the most dependent segments of the lung, especially the upper lobes and the apical segments of the lower lobes, are affected. Primary abscesses are associated with a pulmonary infection, especially due to gram-positive cocci *(S. pneumoniae, S. aureus, S. pyogenes)* and gram-negative bacteria (*P. aeruginosa* and *Klebsiella*). *S. pneumoniae, S. aureus, P. aeruginosa,* anaerobic bacteria, and fungi also cause secondary abscesses.[113]

The initial clinical presentation of a lung abscess is like that of uncomplicated CAP, with fever and cough as the key features. Other common signs are dyspnea, chest pain, anorexia, nausea, vomiting, malaise, and lethargy. A main difference from usual CAP is that it progresses indolently. A typical patient may show tachypnea, dullness to percussion, locally reduced air entry, and localized inspiratory crackles. Plain chest radiography usually confirms the diagnosis. A cavity with thick walls and an air-fluid level is the characteristic finding, although the initial presentation may not be significantly different from a simple consolidation. US is very useful in defining a lung abscess and to differentiate an abscess from a loculated empyema. A contrast-enhanced CT scan is usually considered the investigation of choice, being able to better define a thick wall cavity filled with fluid. It helps to differentiate an abscess from empyema, necrotizing pneumonia, sequestration, pneumatocele, and underlying congenital abnormalities, such as a bronchogenic cyst. It is the usual preferred test to guide an invasive drainage procedure.[113]

The mainstay of treatment is the use of a parenteral antibiotic. There is no controlled trial addressing the duration of antimicrobial therapy, which is usually recommended for 4–6 weeks. Ampicillinsulbactam or a cephalosporin with clindamycin (if CA-MRSA is suspected) are the usual choices to cover the most prevalent pathogens. If an MRSA strain resistant to clindamycin is a possibility, vancomycin should be used.[27,114] In most cases, this will be the only treatment, but interventional radiology-driven drainage or surgery can be considered. The routine use of CT-guided aspiration for abscesses, and the more recent use of CT-guided pigtail drainage catheters at the time of presentation, has been associated with a decrease in the length of hospital stay. Surgery is the last resource after medical therapy has failed.

In a secondary abscess, the outcomes are more closely related to the predisposing factors. In the case of a primary abscess, the prognosis is usually good, no matter the choice of treatment. Complications of lung abscess are empyema, pyothorax, pneumothorax, and, occasionally, bronchopleural fistula.[113,115]

## Prevention

As mentioned earlier, viruses are the most common etiology of childhood pneumonia in populations with high PCV and Hib vaccination coverage.[7] Since respiratory viruses are ubiquitous, complete prevention is difficult. Hygiene measures, such as hand washing and respiratory etiquette, are universally helpful. In health care settings, cohorting and contact isolation, together with droplet precautions, are additional measures that help reduce transmission.[116]

For influenza prevention, annual vaccination with inactivated vaccine is recommended in all children older than 6 months, especially in high-risk groups. Children at an elevated risk of influenza complications include those aged younger than 2 years, those on long-term aspirin therapy, and those with comorbidities (pulmonary, cardiovascular, hematologic, metabolic, neuromuscular, and immunosuppression). Children younger than 8 years should receive two doses at the first year of immunization and one dose per year thereafter. Children aged 9 years or older are considered immunized with a single dose even if receiving influenza vaccination for the first time. An inactivated influenza vaccine has been shown to be more effective than live attenuated vaccines. Antivirals also may be used as chemoprophylaxis under specific situations.[117] For RSV, prophylaxis with a specific monoclonal antibody (palivizumab, IM) is effective in infants at high risk of RSV disease.[118] Several potential vaccines against RSV are under development, although none is approved for clinical use.[119] Live attenuated measles-mumps-rubella and varicella vaccines are recommended to prevent complications, including pneumonitis, especially associated with measles and varicella.[120,121]

*S. pneumoniae* and Hib conjugate vaccines have recently become widely available; however, many children are still not vaccinated globally, especially in low- and middle-income countries. Several studies evaluated the impact of Hib immunization in the prevention of childhood pneumonia, showing reductions of up to 44% in radiology-confirmed cases and up to 100% of bacteremic cases.[20]

Many studies have also reported reductions in clinical and radiological pneumonia, hospitalizations, and mortality due to pneumococcal disease in low- and middle-income and affluent countries following the introduction of PCV, mostly 10- and 13-valent vaccines.[19,122–129] In settings where immunization with the PCV7 was first implemented and switched to the PCV13, further declines in incidence and hospitalization, as well as decreases in complications with empyema, have been observed.[12,13,130–132] The incidence of penicillin-resistant strains of *S. pneumoniae* due to the 19A subtype also decreased after the introduction of PCV13. Nonetheless, replacement with a disease caused by non-PCV serotypes is still a concern.[133,134] Although rare, infection due to PCV-included serotypes can also occur and seems more common in children with comorbidities.[135]

The incidence of pertussis was reduced dramatically after the introduction of immunization. However, its reemergence in recent years has become a public health concern due to waning immunity or the lack of immunization (see Chapter 32).[136] Moreover, prevention strategies for pneumonia in low- and middle-income countries must address a series of important variables that play a role in mortality and morbidity, such as malnutrition, low birth weight, HIV infection, exposure to unprocessed solid fuel, tobacco exposure in the home, poor breastfeeding regimens, and crowding.

Reductions in these risk factors may substantially reduce the incidence of pneumonia in the 21st century.[4,137,138]

# Prognosis

The overall prognosis of pneumonia in most children, especially those who were previously healthy, is complete recovery. A younger age is associated with an increased risk of admission and readmission.[139,140] In high-income countries, death occurs in less than 1 per 1000 patients per year.[7] In low- and middle-income countries, overall mortality can be as high as 65 per 1000 patients per year.[141] Bacterial pneumonia, although less common than viral pneumonia, accounts for a high proportion of deaths.[4] Chronic underlying disease, as well as severe malnutrition and lack of vaccination, are associated with an increased risk of death for both viral and bacterial infections.[141–145] Viral coinfection has a prevalence around 25%–30% of hospitalized children, but it has not been associated with an increased risk of severity, including death.[146] The prognostic significance of viral-bacterial coinfection is unclear, and difficulties in detecting bacteria from the lower respiratory tract remain a challenge.[147]

A systematic review assessing the long-term outcomes of childhood pneumonia with a median follow up of 11 years described a risk of major sequela of 5.5% and 13.6% for outpatients and hospitalized children, respectively.[148] Adenovirus disease was related to an important increase in chronic morbidity (54.8%), and restrictive lung disease was the most common complication. However, a high loss of follow-up in many of the included studies may limit the applicability of these findings.[148] Recently, pneumonia, or LRTI, in the first year of life have been associated with a reduction in lung function at 1 year of age; the effect was compounded by episodes of recurrent pneumonia.[149] Further, an increased risk of wheezing in childhood following pneumonia or LRTI, especially in association with human rhinovirus C and RSV, has been described.[150–153]

# Bronchiectasis and Chronic Suppurative Lung Disease

*Anne B. Chang MBBS, FRACP, MPHTM, PhD, FAAHMS, Gregory J. Redding MD*

## Introduction

Worldwide, there are more people with bronchiectasis unrelated to cystic fibrosis (CF) than with CF and although regarded in affluent countries as an "orphan disease," bronchiectasis remains a major contributor to chronic respiratory morbidity in affluent[1,2] and less affluent countries.[3,4] With the increasing appreciation of bronchiectasis in adults,[5–7] the renewed interest in bronchiectasis has resulted in greater research depth, albeit[7–9] there is still proportionately little research in children. Indeed, bronchiectasis is regarded by the European Respiratory Society[10] as "one of the most neglected diseases in respiratory medicine." This chapter addresses childhood bronchiectasis, chronic suppurative lung disease (CSLD), and protracted bacterial bronchitis (PBB) unrelated to CF. Other underlying pulmonary host defense deficiencies such as ciliary dyskinesia syndromes and immunodeficiencies are covered elsewhere in this textbook.

# Definitions

## Bronchiectasis, Chronic Suppurative Lung Disease, Protracted Bacterial Bronchitis

Bronchiectasis, CSLD, and PBB share common features but are different diagnostic entities with overlaps (Fig. 26.1).[11] Bronchiectasis is a pathologic state of the conducting airways manifested by radiographic evidence of bronchial dilation and clinically by chronic productive cough. Bronchiectasis can be focal with recurrent wet or productive cough and infectious exacerbations, or it can be diffuse, resulting in generalized airway obstruction and destruction with eventual respiratory failure. The diagnostic criteria for bronchiectasis are based on radiographic features of chest high-resolution computerized tomography (c-HRCT), although the sensitivity of adult-defined radiographic criteria has been questioned when applied to children.[12,13] Bronchiectasis may also occur in patients with interstitial lung diseases, because traction on the airways causes secondary bronchial dilation. Traction bronchiectasis in the absence of wet or productive cough will not be considered further.

Progression if left untreated

**FIG. 26.1** Schema of the interrelationship between protracted bacterial bronchitis (PBB), chronic suppurative lung disease (CSLD), and bronchiectasis (BE). "Using the pathobiologic model, PBB, CSLD and radiographic-confirmed bronchiectasis likely represents different ends of a spectrum with similar underlying mechanisms of airway neutrophilia, endobronchial

> bacterial infection and impaired mucociliary clearance. Untreated it is likely some (but not all) children with PBB will progress to develop CSLD and some will ultimately develop bronchiectasis, initially reversible and subsequently irreversible if left to progress. There is a degree of overlap between each of the entities."
>
> (Chang AB, Upham JW, Masters IB, et al. State of the art. Protracted bacterial bronchitis: the last decade and the road ahead. *Pediatr Pulmonol*. 2016;51:225-242; Reproduced with permission from John Wiley and Sons Pediatr Pulmonol 2015; epub ahead doi: 10.1002/ppul.23351.)

CSLD describes a clinical syndrome where symptoms of chronic endobronchial suppuration exist without c-HRCT evidence of bronchiectasis. The presenting symptoms are identical to bronchiectasis, including a prolonged moist or productive cough responsive to antibiotics with or without exertional dyspnea, increased airway reactivity, and recurrent chest infections. The absence of physical signs and symptoms other than wet or productive cough do not reliably exclude either bronchiectasis or CSLD. Lung abscess and empyema (previously included as CSLD) have distinct radiological characteristics and will not be discussed further. Whether bronchiectasis and CSLD are different clinical entities or simply reflect a spectrum of airway disease remains undetermined.[12] Both are chronic suppurative airway diseases and respond to similar treatment regimens.

The sole reliance of radiographic features to distinguish between bronchiectasis and CSLD is in question for several reasons:

1. It is unknown when radiological changes consistent with bronchiectasis occur in the context of a patient with symptoms of CSLD/bronchiectasis. Adult studies have shown that bronchography (the old gold standard for diagnosis of bronchiectasis) is superior to c-HRCT scans in mild disease.[14,15] In the last decade, studies have shown that contiguous 1-mm slices of c-HRCT images identify more bronchiectasis than conventional techniques (1 mm slice every 10 to 15 mm).[16,17] Hill et al. reported that the contiguous 1-mm slices protocol demonstrated 40 extra lobes with bronchiectasis not identified on conventional HRCT in 53 adults.[16] False negative results are more likely to

occur when the disease is mild and localized.[14] Thus, in the current era, tertiary centers generally use multidetector CT (MDCT) scans with HRCT reconstructions used to define airway lesions. It is likely that c-HRCT protocols (without MDCT scans) have insufficient sensitivity to detect early signs of bronchiectasis in some children with symptoms of bronchiectasis.

2. A significant number of children have clinical characteristics of bronchiectasis, but their c-HRCT do not meet the criteria for the adult-based radiological bronchiectasis criteria. c-HRCT findings of bronchiectasis were derived from adult studies,[13] but scans in adults are not necessarily equivalent to those in children. Airway and morphologic changes in the lung occur with maturation and aging.[18] One of the key signs of bronchiectasis is increased bronchoarterial ratio (diameter of the bronchial lumen divided by the diameter of its accompanying artery) of greater than 1 to 1.5. This ratio is influenced by age.[19] Thus, a lower bronchoarterial ratio should be used in children to diagnose bronchiectasis. In young children (aged <5 years), the normal bronchoarterial ratio is around 0.5[20]; and in older children (<18 years), the upper limit is less than 0.8.[13]
3. To fulfill the criteria of "irreversible dilatation," at least two scans are required. Performing more than one c-HRCT scan purely for diagnostic reasons may be impractical and poses safety concerns regarding cancer risks from radiation in children, adolescents, and young adults.[21]
4. The timing of c-HRCT scans to diagnose bronchiectasis is important. Scans performed in different clinical states, such as during an acute pulmonary exacerbation, immediately following treatment, or when clinically stable, may yield different results. C-HRCT scans are ideally performed in a "non-acute state," but this state may differ from a posttreatment state. Bronchial dilatation resolved completely in 6 of 21 children with radiologically defined bronchiectasis when c-HRCT scans were repeated immediately following intensive medical therapy.[22]

Thus, we recommend that HRCT scans are best performed in a nonacute state and bronchiectasis be diagnosed if symptoms of CSLD are present when HRCT findings meet the pediatric[13] rather than adult radiological criteria.

PBB is a condition that is likely a prebronchiectasis state. It was first described as a diagnostic entity in 2006 with clear clinical criteria supported by laboratory studies,[23] although astute clinicians had long recognized PBB-like conditions.[11] PBB is discussed later in the chapter as a separate entity.

# Bronchiectasis and Chronic Suppurative Lung Disease

## Epidemiology, Prevalence, and Burden of Disease

### Prevalence Across Time and Countries

In most affluent countries, the prevalence of childhood bronchiectasis has substantially declined since the 1940s. Field reported on 160 children with bronchiectasis over a 20-year period noting a decline in the incidence from 48 to 10 cases per 10,000 people from the 1940s to the 1960s.[24] By 1994, an English study found that only 1% of 4000 children referred to a respiratory specialty service had bronchiectasis.[25] The reduced incidence over time has been ascribed to reduced crowding, improved immunization programs, better hygiene and nutrition, and early access to medical care. However, bronchiectasis is now increasingly recognized worldwide as an important contributor to chronic respiratory morbidity in less affluent countries[4] and both indigenous[26] and nonindigenous populations in affluent countries.[27] Indeed bronchiectasis is not rare in affluent countries,[1,5,27] but is more common among certain groups for example, the Alaskan Yupik children in the United States, Aboriginals in Australia, and Maori and Pacific Islanders in New Zealand.[26,28] Among these populations, the prevalence of childhood bronchiectasis is 147 to 200 per 10,000 children.[26] A Canadian study conservatively estimated that the prevalence of bronchiectasis among Inuit children living in Nunavut was 20 per 10,000.[29] The only available national incidence data on children is that from New Zealand with a rate of 3.7 per 100,000 under 15 year old children per year,[30] which is almost twice that of CF. In the Northern Territory (Australia with a high proportion of Indigenous people) the incidence in the first year of life is 12 per 10,000.[31]

In adults, the estimated prevalence rate has been increasing (annual change of 8.8% from 2000 to 2007) based on a 5% sample of outpatient Medicare claims in the United States.[32] In the United Kingdom (UK), the prevalence of bronchiectasis in people aged 18 to 29 years increased from 29.3 (95% confidence interval [CI] 20.4 to 41.9) per 100,000 in 2004 to 43.4 (32.3 to 58.4) per 100,000 in 2013.[2] These estimates far exceed the prevalence of CF. Given the need for a CT scan to diagnose bronchiectasis, prevalence or incidence data would be an underestimation. Furthermore, recognition of bronchiectasis is physician dependent and it is not surprising that many cases in children and adults are misdiagnosed as "difficult asthma"[33,34] or chronic obstructive pulmonary disease (COPD). A proportion of adults with COPD (29% of 110) have underlying bronchiectasis.[35] Importantly, the majority of bronchiectasis in adulthood has its roots in childhood.[36,37] One study of adults with bronchiectasis found that 80% of patients had chronic respiratory symptoms from childhood.[38]

Hospitalization rates for adults with non-CF bronchiectasis in the United States have also increased in the last two decades; from 1993 to 2006, the age-adjusted rate increased significantly with an average annual percent increase of 2.4% among men and 3.0% among women.[39] German hospital statistics for 2005–2011 have also increased over that period with an annual age-adjusted rate for bronchiectasis of 9.4 hospitalizations per 100,000 population.[40] Likewise, an Australian state (Queensland) documented an increase in hospitalization from 65 to 83 per 100,000 population between 2005 and 2009.[41]

Data from less affluent countries suggest that bronchiectasis is still associated with poor outcomes, for example, 22% with respiratory failure in a 6.6-year Tunisian follow-up study.[42] Mortality from pediatric bronchiectasis is rarely reported. Arguably, no child without a serious comorbidity should die from bronchiectasis. However, an England and Wales study reported 12 deaths in the 0 to 14 years age group between 2001 and 2007,[43] and 6 (7%) of 91 children died while attending a single New Zealand center between 1991 and 2006.[44] The premature mortality from bronchiectasis may carry over into young adulthood particularly in circumstances with nonoptimal management. This is depicted by a retrospective cohort study of 120 Central Australian Indigenous adults with bronchiectasis (50 diagnosed as children) hospitalized between 2000 and 2006 that reported 34% died during the period at a median age of 42.5 years.[45] In the UK, a recent study described that the crude mortality for men aged 18 to 49 years with bronchiectasis was 13.1 (95% CI 3.4 to 22.8) per 1000 population and 6.4 (0.8 to 12.0) for women compared to the general population, which are rates of 1.3 (1.3 to 1.4) and 0.8 (0.7 to 0.8), respectively.[2] These represent excess mortality rates of 8 to 10 times the general population.

## Economic Cost

There is little data on the economic cost of bronchiectasis and none specific to children. In an United States-based case-control study involving 9146 children and adults (6.7% were aged <18 years), the direct medical cost increased by US$2319 per patient per year relative to the matched control from the preceding year.[46] The cost specifically for children was not described. An earlier study found that in the United States, adults with bronchiectasis averaged 2.0 (95% CI 1.7 to 2.3) additional days in hospital and that the average total annual medical-care expenditures (in 2001) were US$5681 ($4862 to $6593) higher for bronchiectasis patients than age, gender matched controls with other chronic diseases such as diabetes, COPD, and congestive heart failure.[47]

## Other Burden of Disease

In recent years, four pediatric studies in three different continents evaluated the impact of bronchiectasis on the child's and/or parents' health-related quality of life (QoL).[3,48–50] Using the Parent Cough-Specific Quality of Life (PC-QoL)[51] and the Depression, Anxiety and Stress (DASS-21) questionnaires, a Malaysian[3] study described that children with CF had better parental mental health compared to children with non-CF CSLD. Overall, 77% of parents had abnormal DASS-21 scores (54% stressed and 51% depressed).[3] An Australian study[49] examined PC-QoL and DASS-21 scores during the stable-state and exacerbations in 69 children (median age 7 years) and their parents. In the stable state, the median PC-QoL was 6.5 (interquartile range [IQR] 5.3 to 6.9) and DASS-21 was 6 (0 to 20). Both scores were significantly worse during exacerbations (PC-QoL = 4.6 [3.8 to 5.4], $P \leq .001$ and DASS = 22 [9 to 42], $P < .001$).[49] DASS score showed that 38% had elevated anxiety and that 54% had abnormal depression/stress scores during the exacerbation. In the stable state, poorer QoL was significantly recorded with younger children, but QoL did not relate to the radiological extent, lung function, or underlying etiology.[49] In contrast, a Turkish study[48] described that the severity and frequency of symptoms were inversely related to the pulmonary function and the QoL scores (nonpediatric scales were used) in 42 children aged 9 to 18 years. Another Turkish study[50] involving 76 Caucasian children with bronchiectasis and 65 controls used self-reported questionnaires to evaluate the psychological status (using the Child Depression Inventory, State-Trait Anxiety Inventories for Children, and Pediatric Quality of Life Inventories). In this older cohort of children (mean age 11.7, SD 2.6 years), depression and trait anxiety scores were not elevated in those with bronchiectasis, but the child-rated physical health QoL scores were significantly lower in those with bronchiectasis compared to controls.[50] The determinants of QoL were related to age, forced expiratory volume in one second ($FEV_1$)/forced vital capacity (FVC) % predicted, and dyspnea severity.[50]

The differences between the Australian[49] and Turkish[48,50] studies likely relate to the different QoL scales used and severity of disease. It is likely that QoL scores correlate to disease severity only in more severe disease, similar to the relationship between spirometry and radiological extent of bronchiectasis; spirometry is often normal in mild or localized disease,[52] and significant correlations between spirometry indices and radiology scores are seen only in more severe disease.[53] Nevertheless, all studies showed the negative impact of bronchiectasis on the children and/or their parents QoL and mental health. Poor sleep quality has also been reported.[54]

## Etiologic Risk Factors

Bronchiectasis is the result of a variety of airway insults and predisposing conditions that ultimately injure the airways and lead to recurrent or persistent airway infection and destruction. Examples of these conditions are listed in Table 26.1. Bronchiectasis develops in some individuals when structural airway abnormalities, such as bronchomalacia, endobronchial tuberculosis, central airway compression, or retained aspirated foreign bodies impair mucus and bacterial clearance. However, there is currently no evidence of airway malacia causing bronchiectasis in human studies. *Persistent* airway injury and narrowing associated with bronchiolitis obliterans (BO; due to viral injury or following lung transplantation) can lead to bronchiectasis. *Recurrent* airway injury, such as occurs with aspiration syndromes, can also result in bronchiectasis. Selected pediatric cohorts from various settings and countries that describe the frequencies of these associated conditions are summarized in Table 26.2.

### Table 26.1

### Causes of Bronchiectasis

| **Primary Pathophysiology** | **Diseases** | **Major Associations** |
|---|---|---|
| Impaired immune function[a] | Severe combined immunodeficiency<br>Common variable immunodeficiency | Gastrointestinal bacterial infections |
| | Natural killer cell deficiency | EBV infection |
| | Bare lymphocyte syndrome | |
| | X-linked lymphoproliferative disease | |
| | Ectodermal dysplasia | Abnormalities of teeth, hair, eccrine sweat glands |
| | Ataxia-telangiectasia | Cerebellar ataxia, telangiectases |
| | Bloom syndrome | Telangiectasia, altered pigmented skin |
| | DNA ligase I defect | Sun sensitivity |
| | T-cell deficiency | Thymus aplasia |
| | HIV | |
| | Cartilage-hair hypoplasia | Short-limb dwarfism |
| Ciliary dyskinesia | Primary | Sinusitis |
| | Functional | |
| Abnormal mucous | Cystic fibrosis | Pancreatic insufficiency |
| Clinical syndromes | Young's syndrome | Azoospermia |

[a] Although this study was called systematic review, the review was incomplete with several studies omitted.

*CF*, Cystic fibrosis; *GERD*, gastroesophageal reflux disease.

Impaired upper airway defenses may also predispose to bronchiectasis based on the common association between rhinosinusitis and bronchitis/bronchiectasis. Indeed, the sinuses and Eustachian tubes have been considered a "sanctuary site" for bacterial pathogens and cytokines that may predispose to recurrent lower airway infection. Finally, there are variations in host inflammatory responses, for example, cytokine and metalloproteinase levels, and counterbalancing antiinflammatory mechanisms, for example, antioxidants and antiproteases, which may explain why some children develop bronchiectasis, while others do not despite similar exposures and living conditions.[26]

## Previous Acute Lower Respiratory Infections

It is well documented that acute lower respiratory tract infections (ALRIs) in children can lead to subsequent respiratory morbidity and lung function abnormalities.[60,61] Classic epidemiological studies have linked acute ALRIs from adenovirus and other infections with chronic bronchitis and productive cough later in childhood.[62,63]

Recent large epidemiological studies have also shown that those with ALRIs in early childhood are at risk of lower lung function in adulthood.[64,65] Although low lung function at birth may be the underlying factor of the significant association found, single severe ALRIs and multiple ALRIs in early childhood can undoubtedly lead to CSLD and bronchiectasis.[1,66] These single ALRIs associated with bronchiectasis have been described with tuberculosis, pertussis, adenovirus, measles, and severe viral pneumonia. Although these infections do not frequently cause bronchiectasis, they remain common ALRIs in less affluent countries[4] and are still considered important antecedents to childhood bronchiectasis.

In cohort studies, the most common associated cause or ascribed etiology for the bronchiectasis is past pneumonic events with lobar or diffuse alveolar infiltrates (see Table 26.2). In the sole case-control study of childhood pneumonia and radiographically proven bronchiectasis, a strong association between hospitalized pneumonia and bronchiectasis was found.[67] Children who had been previously hospitalized due to pneumonia were 15 times more likely to develop bronchiectasis.[67] A dose effect was also shown; recurrent (>1) hospitalization for pneumonia and more severe pneumonia (episodes with longer hospital stay or oxygen requirement) increased the risk of bronchiectasis later in childhood.[67] Bronchiectasis was 3 times more likely in children with four or five episodes of pneumonia and 21 times more likely if they had 6 or more pneumonias. The overall number of pneumonias rather than the site of pneumonia were associated with bronchiectasis.[67] In an Alaskan cohort, there was no association between lobe affected by first ALRI and the eventually bronchiectatic lobe, but there was an association between lobe most severely affected by ALRI and the lobes later affected by bronchiectasis.[56] Specific infectious etiologies were not described in these studies. A review on the long-term effects of pneumonia in young children[66] described a mixture of obstructive and restrictive lung deficits when followed up long term. However, the majority of studies in the review[66] were limited with case ascertainment and follow-up issues.

Some authors have suggested that bronchiolitis is an important precursor of bronchiectasis. An Alaskan 5-year case-control follow-up of children hospitalized in infancy specifically with severe RSV infections described that they were not more likely to have been diagnosed with bronchiectasis.[68] In contrast, a study of Indigenous children hospitalized with bronchiolitis in Australia found that on CT scans performed at a median 13 months (range 3 to 23) posthospitalization, infants with persistent cough at 3 week (n = 31) after hospitalization were significantly more likely to have bronchiectasis compared to those without a cough (n = 126), OR 3.0, 95% CI 1 to 7, $P = .03$.[69] We surmise that bronchiectasis is not a consequence of specific viruses that produce bronchiolitis.

## Upper Airway Infection and Aspiration

Mechanisms by which upper respiratory infections predispose to lower airway inflammation and injury are reviewed elsewhere.[70] Bacterial pathogens colonizing the nose and mouth are shed into saliva and contaminate the lower airways. Proinflammatory cytokines from the oropharynx may also be aspirated and augment neutrophilic responses in the lower airways. Hydrolytic enzymes in infected upper airway secretions impair protective secretory molecules such as mucins in the lower airways, and thereby predispose the lower airways to infection. *In vitro* studies have shown that some bacteria produce factors that cause ciliary slowing, dyskinesia, and stasis, setting the stage for chronic bacterial colonization of the lower airways.[71] Whether the concentration or persistence of these pathogens in upper airways represents a significant risk factor for development or progression of bronchiectasis is unknown. In indigenous Australian children with bronchiectasis, a study relating nasopharyngeal to bronchoalveolar lavage (BAL) bacteria found a high density and diversity of respiratory bacteria along with strain concordance between upper and lower airways.[72] The study suggests a possible pathogenic role of recurrent aspiration of nasopharyngeal secretions.[72]

Bronchiectasis and other forms of suppurative lung disease have been described among individuals with neurologic and neuromuscular conditions that reduce the frequency and effectiveness of cough and also increase the risk of aspirating oropharyngeal contents. Brook reported on 10 children with such conditions who developed anaerobic pulmonary infections; six had poor oral hygiene.[73]

## Public Health Issues

In 1949, Field wrote "Irreversible bronchiectasis is not commonly seen in the better social and economic classes. Good nutrition and home conditions probably give the child a better chance of more complete recovery from lung damaging disease."[74] Poor public health conditions, including malnutrition, crowding, lack of running water, and environmental pollution, increase the risk of ALRIs and bronchitis.[75,76] These issues are particularly important in developing countries. In affluent countries, those communities with higher prevalence of bronchiectasis are also those where poverty and low standards of housing are common.[26] In a qualitative study, community members and health care providers believed that potential contributing factors to acute and chronic lung diseases were smoke, dust, feeding practices, socioeconomic conditions, and mold.[77]

Macro and selected micro malnutrition increases infection risks, as it creates an immune deficiency state and leads to the malnutrition-infection-malnutrition cycle.[78] However, data on malnutrition specifically preceding bronchiectasis are limited and inconsistent. In Central Australia, Indigenous children with bronchiectasis are 3 times more likely to have had malnutrition in early childhood prior to the diagnosis of bronchiectasis,[67] but this is not seen in Alaska or New Zealand.[26] Breast-feeding is a known protective factor against development of bronchiectasis.[67] Bronchiectasis may itself predispose to malnutrition as a result of chronic pulmonary infection, diminished appetite, and reduced caloric intake. The caloric needs and daily oxygen consumption of children with non-CF-related bronchiectasis have not been reported. One series described that children with bronchiectasis and low (<80%) baseline $FEV_1$ % predicted values, and those with immunodeficiency had significantly lower body mass index at diagnosis, and they significantly improved after appropriate therapy was instituted.[79] Also, in a double-blind randomized controlled trial on the effect of long-term azithromycin, Indigenous children randomized to the azithromycin group (c.f. placebo) had a significant improvement in weight z-score, concurrent with a reduction in exacerbations (incidence rate ratio = 0.5, 95% CI 0.35 to 0.71).[80] This suggests that effective management of children with bronchiectasis improves nutrition.

Another predisposing factor to bronchiectasis is the presence of inhaled irritants, including indoor and outdoor pollutants, particularly in the presence of impaired airway clearance. The effects of environmental tobacco smoke (ETS) on children's respiratory system are well known from both *in utero* and *ex utero* exposure and include reduced airway caliber, increased lower respiratory tract infections, and middle ear disease. Reviews of ETS and its effects on the developing lung and accelerated lung decline are available elsewhere.[81] Exposure to indoor biomass combustion increases coughing illness associated with ALRIs with an exposure-response effect.[82] Exposures to other indoor pollutants (nitrogen dioxide, gas cooking) and traffic are also associated with increased cough in children in both cross-sectional and longitudinal studies.[75] There is no direct evidence of pollutants causing bronchiectasis, and the pathogenic role is likely indirect through an increased frequency of ALRIs and increased airway mucus production. In Chile, increased arsenic exposure has been associated with a variety of chronic disorders including bronchiectasis.[83]

## Genetics

The interplay between genotype, epigenetics, and environment is increasingly recognized as the key in phenotypic expression of respiratory diseases. An increased frequency of cystic fibrosis transmembrane conductance regulator (CFTR) genotypes associated with CF, presenting as heterozygotes, has been described in several case series of adults with diffuse bronchiectasis.[84] While heterozygotes for alpha-1 antitrypsin have also been described more frequently in those individuals with diffuse bronchiectasis, a causal relationship remains controversial. Older guidelines suggest optional screening for alpha-1 antitrypsin deficiency for patients with idiopathic diffuse bronchiectasis,[85] but newer guidelines described a lack of evidence and do not suggest alpha-1 antitrypsin deficiency testing for people with bronchiectasis.[86] A Turkish study (where consanguinity of parents is common) described transporter associated with antigen presentation (TAP) gene polymorphisms in their cohort of children with bronchiectasis.[87] It is interesting to note the high rate of consanguinity in several series of children with bronchiectasis from different countries.[88,89] As with other diseases, an increasing number of gene aberrations have been associated with syndromes where bronchiectasis may occur. Examples include primary ciliary dyskinesia, autosomal dominant polycystic kidney disease (PKD1 on chromosome 16p13.3 and PKD2 on chromosome 4p21),[90] and prolidase deficiency[91] (PEPD gene).

Aside from variations in specific gene frequencies, overexpression of innate pulmonary immune mechanisms, such as proinflammatory cytokine and adhesion molecule production, and receptor expression, may contribute to the development of bronchiectasis in certain children. An increased or exaggerated neutrophilic response in Australian Indigenous children as a group has been described.[92] Similarly, metalloproteinases, for example, MMP-2 and 9, have been isolated from the sputum and BAL of bronchiectatic subjects, suggesting a role in airway destruction by gelatinases and collagenases.[93,94] Whether proinflammatory cytokine and collagenase overexpression are associated with early onset disease or, particularly, progressive disease in childhood remains unknown.

## Pathology and Pathophysiology

The histopathology of bronchiectasis was first described by Laënnec[95] in 1819. It includes alterations in subsegmental bronchial structure accompanied by neutrophilic inflammation, intraluminal secretion accumulation, and obliteration of distal airways. There are accompanying changes of peribronchial inflammation and fibrosis, distal lung collapse, bronchial and pulmonary vascular changes, and pleural adhesions. The macroscopic and microscopic features of bronchiectasis change as the disease progresses. Classical papers on bronchiectasis divided morphological types of bronchiectasis into tubular or cylindrical, early fusiform, late fusiform, fuso-saccular, and saccular types as different stages in the progression of disease.[36] The most commonly used classification is that of Reid's subtypes: cylindrical, varicose and cystic,[96] which were based on bronchographic findings. The latter findings are illustrated in Figs. 26.2 and 26.3 and they reflect progression of increasing severity. More recent HRCT scoring systems describe cylindrical and saccular changes as markers of disease severity.[97] Saccular and cystic changes tend to reflect clinically more advanced, severe, and irreversible disease.

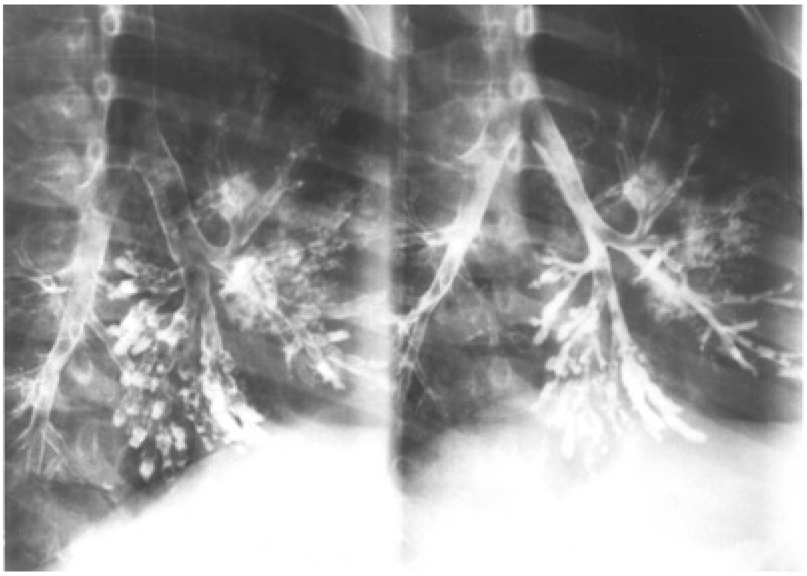

**FIG. 26.2** Varicose and cystic changes characteristic of severe bronchiectasis by bronchogram.

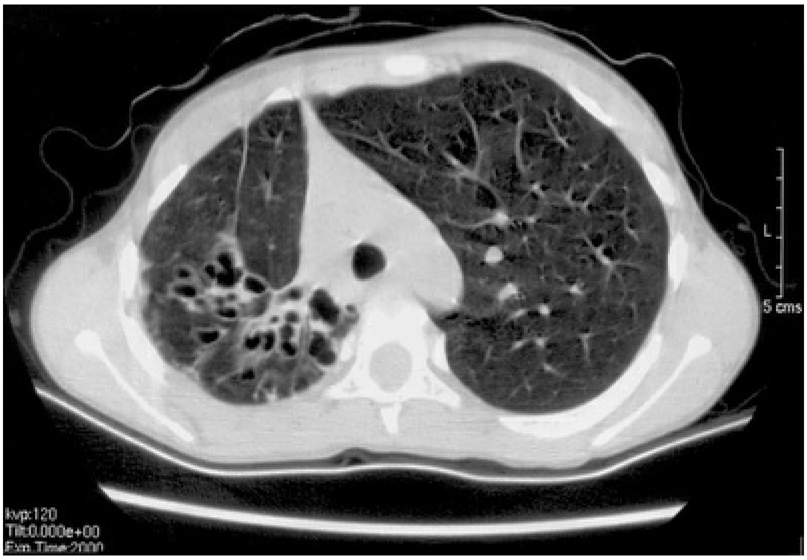

**FIG. 26.3** CT scan findings of saccular bronchiectasis in the right upper lobe of a 9-year-old boy.

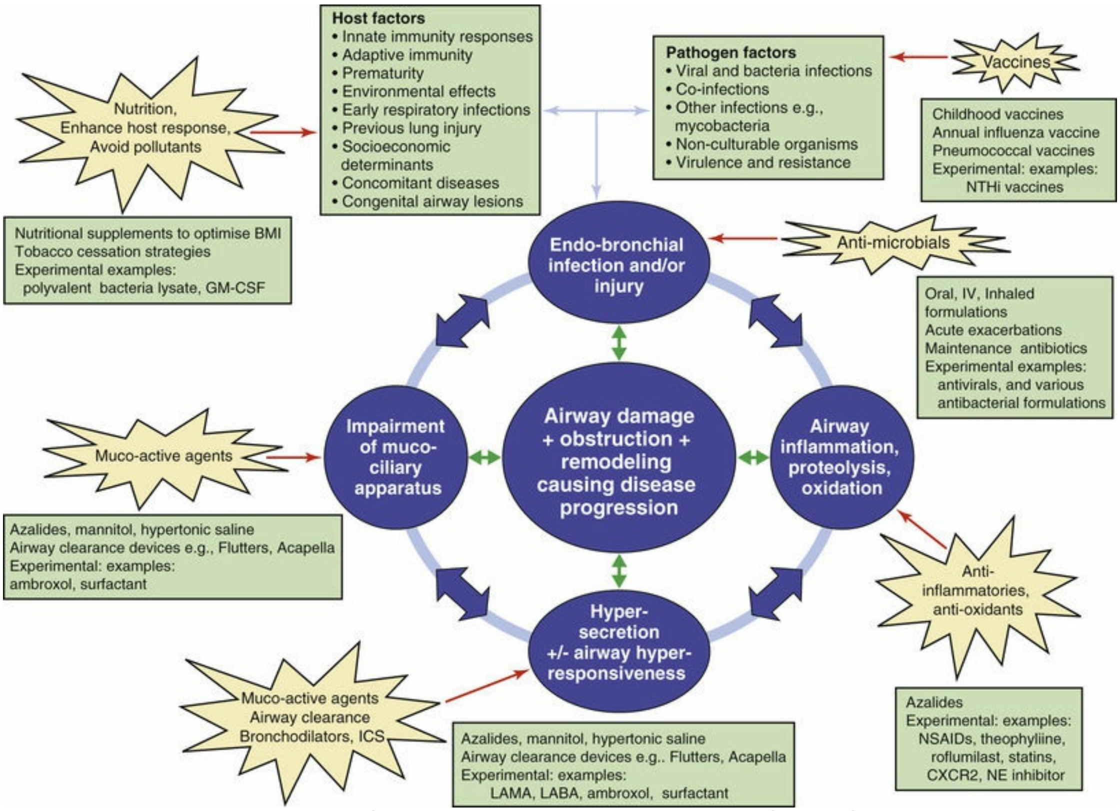
Macroscopically, the airways are tortuous and dilated, at times extending to the pleural surface. Early histologic changes include bronchial wall thickening, edema, presence of inflammatory cells, development of lymphoid nodules and follicles, and mucus gland hyperplasia. Intraluminal secretions are purulent or mucopurulent (Video 26.1▶). Microscopic changes include loss of ciliated epithelial cells and epithelial ulcerations. With time, chronic inflammation leads to squamous cell metaplasia and fibrotic obliteration of distal conducting airways and peribronchial tissue. As bronchiectasis becomes more severe, the airway walls become thin and saccular with destruction of the airway's muscular, elastic, and cartilaginous elements.[96,98] The saccular airway walls are composed of fibrous and granulation tissue with only remnants of normal tissue. In advanced disease, mucus-filled saccular airway changes can be severe enough to appear as cystic microabscesses.

Vascular changes accompany bronchial structural changes in bronchiectasis. Large bronchopulmonary anastomosis can develop, and total bronchial arterial blood flow is increased. Extensive precapillary anastomoses between the two arterial systems can serve as a shunt between the pulmonary and systemic systems, increasing cardiac work.[98] Bronchopulmonary vascular anastomoses most often occur near distal subsegmental bronchi that have undergone saccular changes. Abnormal bronchopulmonary anastomoses and enlargement of aberrant bronchial arteries are thought to be associated with the metabolic demands of hypertrophied muscle, lymphoid tissue, and peribronchial granulation tissue during the course of the organizing pneumonitis that precedes the development of bronchiectasis.[99] The presence of significant hemoptysis is likely related to these abnormalities. Additional vascular remodeling of the pulmonary arteries and arterioles occurs in association with chronic airway obstruction and alveolar hypoxia, predisposing patients to pulmonary hypertension and cor pulmonale in severe cases.

The initial trigger for the bronchiectasis process is unknown, and there is little doubt that both host and pathogen factors play a role (Fig. 26.4). Animal models of bronchiectasis suggest that inadequate mucus clearance and persistent infection are necessary prerequisites.[101] Mucus clearance in bronchiectasis is reduced by a combination of factors including airflow limitation,[102,103] abnormal quantity and quality of mucus produced,[104] and factors produced by bacteria that cause ciliary slowing, dyskinesia, and mucus stasis.[71] Mucociliary clearance is enhanced by cough, exercise, and hyperventilation,[103,105,106] and is decreased in situations where airway caliber is diminished.[102,103] Decreased mucociliary clearance in turn leads to increased bacterial colonization and infection, setting up a vicious cycle. This concept is schematically presented in Fig. 26.4. Importantly, reduced mucociliary clearance is localized to the affected regions when bronchiectasis is produced by local injury rather than underlying deficiencies in pulmonary host defenses.[107] The role of bacteria in the pathogenesis of chronic lung infection and bronchiectasis is reviewed elsewhere.[8,108,109]



Host factors
• Innate immunity responses
• Adaptive immunity
• Prematurity
• Environmental effects
• Early respiratory infections
• Previous lung injury
• Socioeconomic determinants
• Concomitant diseases
• Congenital airway lesions
Pathogen factors
• Viral and bacteria infections
• Co-infections
• Other infections e.g., mycobacteria
• Non-culturable organisms
• Virulence and resistance
Vaccines
Childhood vaccines
Annual influenza vaccine
Pneumococcal vaccines
Experimental: examples: NTHi vaccines
Nutrition, Enhance host response, Avoid pollutants
Nutritional supplements to optimise BMI
Tobacco cessation strategies
Experimental examples: polyvalent bacteria lysate, GM-CSF
Endo-bronchial infection and/or injury
Anti-microbials
Oral, IV, Inhaled formulations
Acute exacerbations
Maintenance antibiotics
Experimental examples: antivirals, and various antibacterial formulations
Muco-active agents
Impairment of muco-ciliary apparatus
Airway damage + obstruction + remodeling causing disease progression
Airway inflammation, proteolysis, oxidation
Azalides, mannitol, hypertonic saline
Airway clearance devices e.g., Flutters, Acapella
Experimental: examples: ambroxol, surfactant
Anti-inflammatories, anti-oxidants
Hyper-secretion +/- airway hyper-responsiveness
Muco-active agents
Airway clearance
Bronchodilators, ICS
Azalides, mannitol, hypertonic saline
Airway clearance devices e.g.. Flutters, Acapella
Experimental: examples: LAMA, LABA, ambroxol, surfactant
Azalides
Experimental: examples: NSAIDs, theophyliine, roflumilast, statins, CXCR2, NE inhibitor

**FIG. 26.4** A simplified schematic diagram of the factors contributing to the development of bronchiectasis. The initial trigger causing persistence of endobronchial infection and injury is dependent on host, environmental, and pathogen factors. This infection leads to inflammation, proteolysis, oxidation and subsequent mucous hypersecretion and/or airway

hyperresponsiveness, with impairment of the mucociliary apparatus. Each factor influences each other (as in Cole's vicious cycle postulate)[100] and may lead to development, or increasing severity, of bronchiectasis (central circle) if left untreated. Possible therapeutics affecting each factor are presented in the jagged shapes. *BMI,* Body mass index; *CXCR2,* CXC chemokine receptor 2 antagonist; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *ICS,* inhaled corticosteroids; *IV,* intravenous; *LABA,* long acting beta$_2$-adrenoceptor agonist; *LAMA,* long acting muscarinic antagonists; *NE,* neutrophil elastase; *NTHi,* nontypeable *Haemophilus influenzae.*

## Airway and Systemic Markers

The majority of studies on airway inflammation have been performed in adults where, unlike children, assessment by using sputum is easy. Airway secretions are usually excessive in those with more severe bronchiectasis. The sputa from Alaskan native children with stable idiopathic bronchiectasis are less viscous (by one-third), less elastic (by one-fifth), less adhesive (by half), and more transportable (by 50%) compared to sputum from children with CF.[110]

Neutrophilia is the dominant type of airway inflammation,[58] although eosinophilia has also been described in some populations[111] and when treated, airway inflammation may be absent.[58] Increased percentages of neutrophils, neutrophil elastase, myeloperoxidase, mellatoproteinases, tumor necrosis factor-$\alpha$ (TNF-$\alpha$), interleukin (IL-8), and IL-6 have been described in lower airway secretions.[112] These generally reflect neutrophilic inflammation and are not specific to bronchiectasis. The intensity of the airway and systemic inflammation is ameliorated by treatment.[112,113] An adult cohort involving 385 patients described a direct relationship between airway bacterial load and markers of airway inflammation (myeloperoxidase, neutrophil elastase, TNF-$\alpha$, IL-8, and IL-1β) with a dose response such that higher inflammation correlated with higher bacterial loads.[112] High bacterial loads were associated with higher serum intercellular adhesion molecule-1 (ICAM-1), E-selectin, and vascular cell adhesion molecule-1 (VCAM-1), reflective of systemic inflammation. Using both short (14 days)- and long (12 months)-term antibiotic treatments, the study demonstrated a significant reduction in the airway bacterial load and inflammation (both airway and systemic) compared to those who did not receive antibiotic therapies.[112] However, there is a poor correlation between systemic and bronchial inflammatory mediators, suggesting that the inflammatory process is mostly compartmentalized to the airways.[114] There is paucity of data on BAL or sputum markers in children. A small study in children described increased median values of systemic markers (white cells, C-reactive protein [CRP], and fibrinogen) in children whose airways were colonized (n = 14) compared to those without identified bacteria in their sputum (white cell count: 8.2 [IQR 6.4 to 9.5] vs. 6.4 [5.8 to 7.7] × $10^3/mm^3$; CRP: 0.91 [0.45 to 1.29] vs. 0.42 [0.30 to 0.77] mg/dL; fibrinogen: 433.5 [390.3 to 490.3] vs. 392.0 [327.0 to 416.0] mg/dL, $P < .05$ for all).[115] While the authors concluded that systemic inflammation was absent in children with bronchiectasis compared to controls, it is highly likely that a type-1 error was present in the study. In an in-depth study, the blood of children with bronchiectasis had a significant increase in the percentage of CD8+ T cells and T and natural killer T-cells (NKT)-like subsets expressing perforin/granzyme, interferon gamma (IFN$\gamma$), and TNF$\alpha$ compared with controls.[116] The proinflammatory cytotoxic T cells were more marked in Indigenous children compared to non-Indigenous children.[116]

Exaggerated or persistent pulmonary inflammation present in bronchiectasis leads to increased lung destruction by many mechanisms.[8] The balance between proteases and antiproteases is increasingly recognized as important to the protection of airways against hostile agents and destruction of lung tissue. Upregulation of circulating adhesion molecules (E-selectin, ICAM-1, and vascular adhesion molecule VCAM-1) have also been suggested as playing a role in the pathogenesis of bronchiectasis.[117] Collagenase activity present in the BAL of adults with moderately severe bronchiectasis originates from neutrophils and bacteria. These collagenolytic proteases are likely contributors to tissue destruction.[118] As described above, the airways of people with bronchiectasis contains collagenolytic proteinases of bacterial origin.[118] and neutrophilic-associated cytokines that, unabated, lead to increased tissue damage (e.g., metalloproteinases [MMP-2,8, and 9]).[117] MMP-9 (but not tissue inhibitors of metalloproteinase-1) measured in exhaled breath condensate of children with non-CF bronchiectasis (42.8 ± 18.1 ng/mL) were similar to those with CF (48.9 ± 26.8) and significantly higher than controls (30 ± 3.7).[119] Endobronchial biopsies in adults with bronchiectasis demonstrated an overexpression of neutrophil matrix metalloproteinases (MMPs).[117] Using sputum from adults with bronchiectasis, Shum et al. showed that serine proteases derived from neutrophils were responsible for degradation of proteoglycans in a matrix model and that the protease secretion was stimulated by TNF-$\alpha$ in the presence of factors found in the sputum sol.[120]

There are additional pathogenic processes associated with bronchiectasis that contribute to the persistence of airway inflammation and obstruction. Increased airway permeability has also been described with bronchiectasis when purulent sputum and significant colonization of the respiratory tract by bacterial pathogens are present.[121] Also, resolution of inflammation is normally associated with the orderly removal of apoptotic inflammatory cells, and impaired removal of apoptotic inflammatory cells has been described in children[122] and adults[123] with bronchiectasis. The pediatric study[122] also examined specifically for phagocytic activity for nontypeable *Haemophilus influenzae* (NTHi), whereas the adult study[123] investigated apoptosis in relation to inflammation. The adult study[123] reported that impaired apoptosis occurred in a dose-response fashion with increasing neutrophil elastase, a marker of neutrophilic inflammation. In children with bronchiectasis, the macrophage phagocytic capacity of BAL cells to apoptotic cells (efferocytosis) and to NTHi was significantly lower than in controls (efferocytosis: 14.1%, IQR 10 to 16 vs. 18.1%, IQR 16 to 21 respectively, $P < .001$ and NTHi: 13.7%, IQR 11 to 16 vs. 19.0%, IQR 13 to 21 respectively, $P = .004$).[122] Mannose receptor expression in BAL was also found to be significantly reduced in the bronchiectasis group compared to controls ($P = .019$).[122]

### Other Immune Markers and Response

Innate defense mechanisms also play a role in the pathogenesis and upregulated response to infection in people with bronchiectasis.[8] However, there is little data specific to children.[27] In a study involving 26 children with human immunodeficiency virus (HIV)-related bronchiectasis,[124] the soluble triggering receptor expressed on myeloid cells-1 (sTREM-1), an innate immune marker, was upregulated and more highly expressed than in children with CF. sTREM-1 also correlated with IL-8 and neutrophil elastase derived from BAL.[124]

The increased expression of innate immune receptors (e.g., receptors TLR2, TLR4, and CD14) and cytokine responses (e.g., IL-8 and IL-1β) seen in adults with bronchiectasis are also found in those with neutrophilic asthma and children with PBB,[125,126] a likely forerunner of bronchiectasis.[11] This raises the possibility that some people with neutrophilic asthma have unrecognized CSLD. Indeed, many of children with PBB were previously misdiagnosed with asthma[11,34] and in some settings has been classified as “difficult or severe asthma.”

There is an emerging body of evidence that impaired cell-mediated immune responses and dysregulated airway inflammation are linked and could contribute to the pathobiology of CSLD. A study on systemic immunity found that children with CSLD or bronchiectasis produced significantly less IFN-γ in response to NTHi than healthy control children, whereas mitogen-induced IFN-γ production was similar in both groups.[127] The production of systemic NTHi-specific IFN-γ was significantly negatively associated with the BAL IL-6 ($P = .001$) and IL-1β ($P = .001$).[128] The presence of bacterial or viral infection and severity of bronchiectasis using modified CT Bhalla score did not influence systemic NTHi-specific IFN-γ response.[128]

## Clinical Features

### Presenting Clinical Features: Symptoms and Signs

The clinical case definition of bronchiectasis is imprecise, but the diagnosis should be considered when children have a chronic “wet” sounding or productive cough with or without exertional dyspnea, recurrent wheezing and chest infections, hemoptysis, growth failure, clubbing, or hyperinflation. The most common symptom is persistent or recurrent wet/productive cough with purulent or mucopurulent sputum. Sputum color reflects neutrophilic airway inflammation.[129,130] The frequency of chest wall deformity (hyperinflation) and digital clubbing vary among case series (5% to 60%).[24,52,131] Digital clubbing can disappear after medical or surgical treatment in association with the disappearance of purulent sputum.[24,131] Although hemoptysis is much less common among children than in adults with bronchiectasis, a presenting finding of hemoptysis should raise the possibility of airway bleeding due to bronchiectasis. Chest auscultation may be entirely normal or reveal coarse inspiratory crackles over the affected regions. Reduced oxygen saturations and abnormal cardiac sounds associated with pulmonary hypertension are very late signs in bronchiectasis. Similar to any other serious chronic respiratory illness, children with bronchiectasis may have growth failure[52] that is associated with delayed diagnosis of bronchiectasis.

The median age of diagnosis of bronchiectasis unrelated to CF in affluent countries is 4 to 5 years.[52,56] A New Zealand cohort[55] was older at 9 to 10 years old at diagnosis but also experienced more advanced disease. Idiopathic bronchiectasis is rare in infancy, but when present, it is likely to reflect congenital pulmonary malformations, such as cystic lung disease or tracheobronchomegaly, or alternatively, primary ciliary dyskinesia. Only 50% of those with ciliary dyskinesia have the Kartagener triad of situs inversus, bronchiectasis, and sinusitis.[132]

Radiological risk factors for development of bronchiectasis are the presence of atelectasis[67,133] and persistent lobar abnormalities.[134] In Alaska, children were more likely to develop bronchiectasis if chest radiographs obtained in children less than 2 years of age showed lung parenchymal densities, persistent parenchymal densities greater than 6 months duration, or repeated parenchymal densities.[134] Among Aboriginal Australian children hospitalized with lobar changes on admission chest radiographs, children with alveolar abnormalities were more likely to have bronchiectasis on follow-up.[133] In a prospective radiographic study of alveolar changes (179 lobes in 112 hospitalized children), the two most common involved lobes were the right upper lobe and left lower lobes.[133] Both lobes had similar rates of radiological clearance on follow-up (22% and 27% respectively).

## Comorbid Conditions

Children with postinfectious bronchiolitis obliterans and CSLD share some common clinical features (airway obstruction, chronic cough, recurrent ALRIs) in addition to the same etiological insult.[60,135] In an Australian study, 6 of 19 children with postinfectious BO developed bronchiectasis.[60] A South American cohort follow-up study (mean period of 12 years, SD 3.5) described that mean FVC increased by 11%/year (95% CI 9.3 to 12.6), $FEV_1$ by 9%/year (95% CI 7.7 to 10.2), and $FEV_1$/FVC ratio decreased by 1.9%/year (95% CI 1 to 2.8).[136] Seventy-eight percent of the 46 children in that cohort had bronchiectasis.[136]

Phenotypes of childhood wheeze have been recognized and airway hyperreactivity occurs in some individuals with bronchiectasis.[135] The presence of features of asthma has been described as a bad prognostic factor in both children[24,131] and adults[137] with bronchiectasis. The frequency of airway hyperreactivity in children with bronchiectasis varies from 26% to 74%.[52,56] As a corollary, clinicians must recognize that wheeze and cough may not be related to asthma but to increased airway secretions and airway collapse as features of bronchiectasis.

Gastroesophageal reflux disease (GERD) may coexist with any chronic respiratory illness and should be appropriately treated. However, data in adults indicate that GERD may resolve or significantly improve once the underlying respiratory disorder has been treated.[138] There is, however, no evidence-based approach to the management of GERD associated with bronchiectasis. Caution is necessary with regard to overdiagnosis, and unnecessary treatment of GERD is given the increasing evidence of increased risk of respiratory infections in children and adults receiving proton pump inhibitors in community and hospital cohorts.[139,140] Readers are referred to the pediatric guidelines on diagnosis and treatment of GERD.[141]

Hypertrophic osteoarthropathy (clubbing, periostosis of the tubular bones, and arthritis-like signs and symptoms) may occur in children with bronchiectasis.[142] Systemic amyloidosis has also been reported as a complication or comorbidity.[143] Cardiac dysfunction, although rare, has also been reported and may not be accompanied by pulmonary hypertension. A study of 21 children with bronchiectasis showed that the ventricular systolic function was normal but some patients had changes in left ventricular diastolic function.[144] The authors also found that isovolumetric relaxation time had a significant negative correlation with the clinical severity score. Other reported comorbid conditions associated with bronchiectasis are osteopenia,[145] scoliosis, chronic suppurative ear disease, social problems, past urinary tract infections, and developmental delay.[52,56]

In adults, vitamin D deficiency has been reported to be associated with increased severity of bronchiectasis and chronic bacterial colonization of the airways.[146] However, as serum vitamin D is a negative acute phase reactant (i.e., values fall with increased inflammation), deciphering cause and effect is problematic.[147]

## Diagnostic Evaluations

The goals of evaluating children with suspected bronchiectasis are: (1) to confirm the diagnosis, (2) to define the distribution and severity of airway involvement, (3) to characterize extrapulmonary organ involvement associated with bronchiectasis (such as cor pulmonale), and (4) to identify familial and treatable underlying causes of bronchiectasis and contributors to its progression.

### Diagnostic Criteria

Chest HRCT is the gold standard for diagnosis,[27] because plain chest radiographs are insensitive. It has been long recognized that chest x-rays can be normal in people with bronchiectasis.[148] With modern CT scanners, the images are best acquired using an MDCT scan with HRCT reconstruction which provides the best sensitivity.[27] The scan protocol must be child-appropriate to minimize radiation risk. Radiology centers inexperienced in dealing with children often utilize adult protocols that subject children to higher doses of radiation. Radiological features of bronchiectasis can also occur in association with pulmonary fibrosis, congenital lesions such as Mounier-Kuhn, and Williams-Campbell syndrome,[97] and as a result of traction in nonsuppurative lung disease.[149]

The characteristic radiographic finding on HRCT in bronchiectasis is the presence of a "signet ring" where a dilated bronchus is greater than the diameter of the accompanying blood vessel in cross section (Fig. 26.5).[97,150] However, the cutoff (>1 to 1.5) whereby the ratio is considered abnormal should be reduced to 0.8 in children when CSLD symptoms are present.[13] While this is generally appreciated by pulmonologists, radiologists may still use the adult criteria. The presence of bronchial dilatation relative to the accompanying vessel does not always equate to the presence of bronchiectasis, as this finding can also be present in other conditions (Box 26.2). Other c-HRCT signs of bronchiectasis include abnormalities in the surrounding lung may include parenchyma loss, emphysema, scars and nodular foci,[150] a linear array or cluster of cysts, dilated bronchi in the periphery of the lung, and bronchial wall thickening (Box 26.1).[154] Image quality and hence detection of bronchiectasis is dependent on the radiological technique used (tube setting, radiation dose, collimation distance, and image intervals).[155] False positive and false negative situations that may occur are listed in Box 26.2. HRCT does not differentiate the etiologies of bronchiectasis.[156]

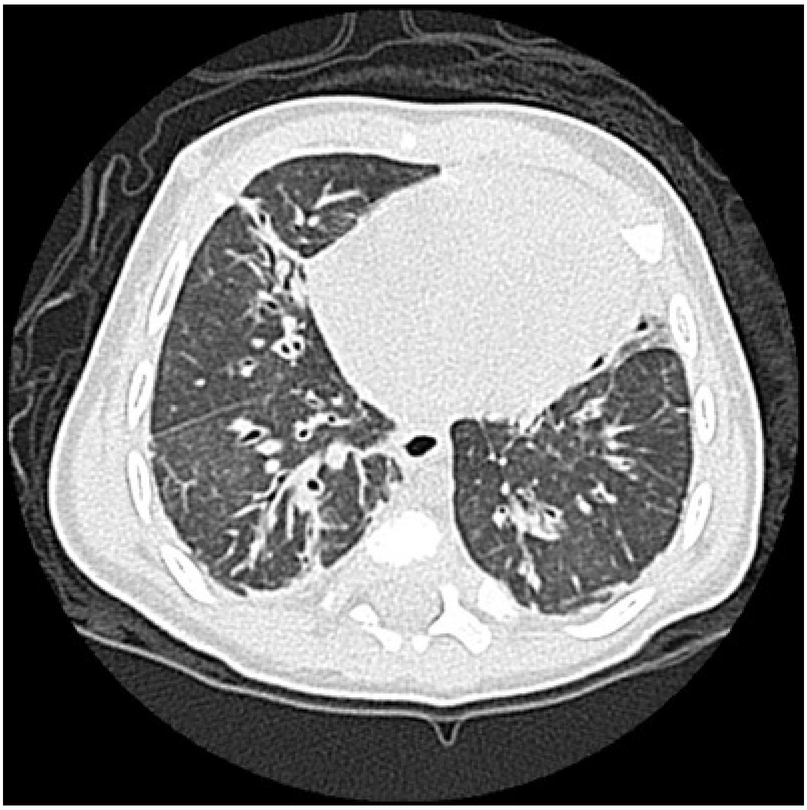


**FIG. 26.5** High resolution CT finding in bronchiectasis. Image illustrates the "signet ring" appearance of a dilated airway adjacent to smaller associated pulmonary vessels. In adults, abnormal dilatation is considered present when the bronchoarterial ratio (inner diameter of bronchus: external diameter of adjacent artery) is greater than 1. In children, a cutoff of 0.8 is considered abnormal when clinical features of bronchiectasis are present.

**Box 26.1**

## Features of Bronchiectasis on Chest High Resolution Computed Tomography Scans

1. Signet ring sign: internal diameter of bronchi is larger than accompanying vessel (diameters of both should be short axis)
2. Enlarged internal bronchial diameter
3. Failure of airway to taper normally while progressing to lung

periphery
4. Presence of peripheral airways at CT periphery
5. Presence of associated abnormalities
    - Bronchial wall thickening
    - Mucoid plugging or impaction (seen as branching or rounded/nodular opacities in cross sections, tubular or Y-shaped structures or tree in bud appearance)
6. Mosaic perfusion
7. Air trapping on expiration
8. Air-fluid levels in distended bronchi

Compiled from references 97, 151-153.

**Box 26.2**

## Pitfalls in Diagnosis of Bronchiectasis on Chest High-Resolution Computed Tomography Scans

### False Positives

1. Physiologic constriction of pulmonary artery (creates relative bronchial enlargement)
2. Artefacts from cardiac pulsation and respiratory motion (creates pseudocystic pattern)
3. Pseudobronchiectasis or transient bronchial atresia (related to acute pneumonia or atelectasis)
4. Increased bronchoarterial ratio in normals, asthmatics or at high attitude

### False Negatives

1. Inappropriate HRCT protocol (wrong electronic windows or collimation)
2. Poor image due to movement artefacts
3. Nonuse of high-resolution techniques

*HRCT,* High-resolution computed tomography.

Compiled from references 97, 151-153.

## Etiologic Evaluation

As most patients are usually diagnosed with bronchiectasis after many years of symptoms, it may be difficult to define the etiology. Differentiating idiopathic from postinfectious bronchiectasis is particularly problematic. A common feature of many patients is impaired local or systemic host defenses to infection.[127,157] Often, no cause is found even with extensive investigation, and many retain the label of idiopathic or presumed postinfectious bronchiectasis (see Table 26.2). Difficulties with ascribing an etiology to CSLD/bronchiectasis arise due to unavailability of certain tests, for example, functional tests for ciliary motility and extended immune testing, lack of a standardized approach to diagnosis, the population studied, and the CT definitions used.

Identifying etiology and assessing disease severity can influence surveillance frequency, treatment intensity, and prognosis.[157,158] Investigations for specific causes of CSLD/bronchiectasis are recommended, even though many patients will lack an identifiable etiology.[79] Current best practices for investigating possible etiology are outlined in Table 26.3. The diagnosis of ciliary dyskinesia[159] is addressed in another chapter (see Chapter 71).

### Table 26.3

### Evaluation for Underlying Etiologies

| Investigation Type | Details | Evaluation for: |
|---|---|---|
| **ROUTINE** | | |
| Baseline immune function | IgG, A, M, IgG subclasses, IgE, hemagglutinins, antibodies to vaccinations | Immune deficiency states |
| Full blood count | White cell count | Neutropenia |
| HIV status | HIV antibody, HIV PCR assay | HIV infection |
| Sweat test and consider genotype | Sweat chloride and CF genotype | Cystic fibrosis |
| Radiology | Chest HRCT scan<br>Chest radiograph | Diagnosis, congenital malformation and disease severity |
| Aspergillosis serology | Aspergillus specific IgE<br>Skin test, total IgE | Allergic bronchopulmonary aspergillosis |

| | | |
|---|---|---|
| Cilial biopsy and consider genetic testing | Electron microscopy and ciliary beat function | Ciliary dyskinesia |
| Sputum | Microscopy, sensitivity and culture | Number of polymorphs, microbiology |
| **ADDITIONAL TESTS DEPENDING ON CLINICAL CHARACTERISTICS** | | |
| Bronchoscopy | Airway abnormalities<br>BAL | Obstructive bronchiectasis<br>Congenital airway abnormalities<br>Microbiological assessment when sputum cannot be obtained<br>Cellular differential count |
| Investigations for GERD | Esophageal pH studies, manometry and/or upper endoscopy | GERD with or without aspiration syndromes |
| Barium meal | | Tracheoesophageal fistula, esophageal abnormalities causing secondary aspiration such as achalasia |
| Mantoux | PPD tuberculin and atypical | Mycobacterium TB and atypical mycobacteria |
| Further immune tests | Neutrophil function, CH50, etc. | Immune function |
| Video fluoroscopy | Oro-palatal function and assessment of laryngeal protection | Primary aspiration lung disease |
| Genetic tests | | |

*BAL,* Bronchoalveolar lavage; *GERD,* gastroesophageal reflux disease; *HRCT,* high-resolution computed tomography; *PPD,* purified protein derivative skin test; *TB,* tuberculosis.

## Bronchoscopic Findings

Bronchoscopy is indicated to identify obstructive bronchiectasis, which can be intraluminal (tumors and foreign body), in the wall (tracheobronchomalacia [TBM]), or extramural from external airway compression. Bronchiectasis is a complication of inhaled foreign bodies and occurs among 25% of patients whose diagnosis of aspiration was delayed by greater than 30 days.[160] In a prospective study involving 56 children with bronchiectasis undergoing flexible bronchoscopy, there were 25 occasions in 23 children where bronchoscopic results altered empiric treatment.[111] BAL microbiology results led to antibiotic changes in five (9%) children, and an unsuspected foreign body was found in one (2%).[111]

Bronchoscopic findings of major airways related to bronchiectasis have been described as five types: type I: mucosal abnormality/inflammation only; type II: bronchomalacia (Fig. 26.6A); type III: obliterative-like (Fig. 26.6B); type IV:

malacia/obliterative-like combination; and type V: no abnormality.[161] The frequencies of these findings among 28 children with non-CF bronchiectasis were 58%, 17%, 17%, 4%, and 2% for types I through V respectively.[161] In the 33 children with postinfectious bronchiectasis and CSLD, structural airway lesions were present in 40%.[161] A retrospective study involving 93 Greek children (0.6 to 16.4 years) described that type III (OR 5.4, 95% CI 1.9 to 15.4) and type IV (OR 8.9, 95% CI 2.5 to 15.4) bronchoscopic lesions significantly correlated to worse radiological scores, reflecting severity, and correlated with the percentage of BAL neutrophils (r = 0.23, *P* = .036).[162]

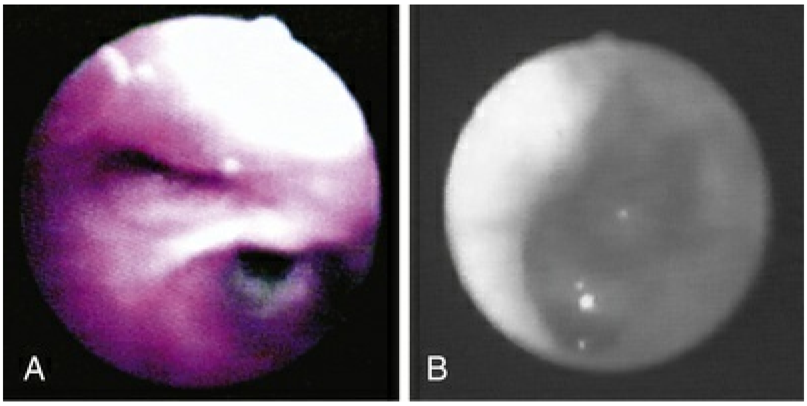

**FIG. 26.6** Major airway bronchoscopic findings in bronchiectasis. (A) Bronchomalacia (airway type II) of the right middle lobe. (B) Obliterative-like lesion (airway type III) seen in the segmental bronchi (middle of picture) while the adjacent bronchi are widely patent and more inflamed. (Reproduced with permission from the BMJ Publishing Group—Chang AB, Boyce NC, Masters IB, et al. Bronchoscopic findings in children with non-cystic fibrosis chronic suppurative lung disease. *Thorax* 2002;57:935-938.)

Bronchomalacia associated with bronchiectasis can be related to chronic inflammation,[163] although it is unknown if bronchomalacia predates recurrent respiratory infections. Airway mucosal changes typical of chronic bronchitis are usually present in bronchiectatic airways at bronchoscopy. Bronchoscopic findings include atrophic mucosa, increased secretions, and airway friability. Airway flaccidity, hypertrophy of elements in wall, longitudinal corrugations, mucosal reddening, increased vascularity, dilated ducts, and displacement due to lobar collapse have also been described in the proximal conducting airways (Fig. 26.7).[163]

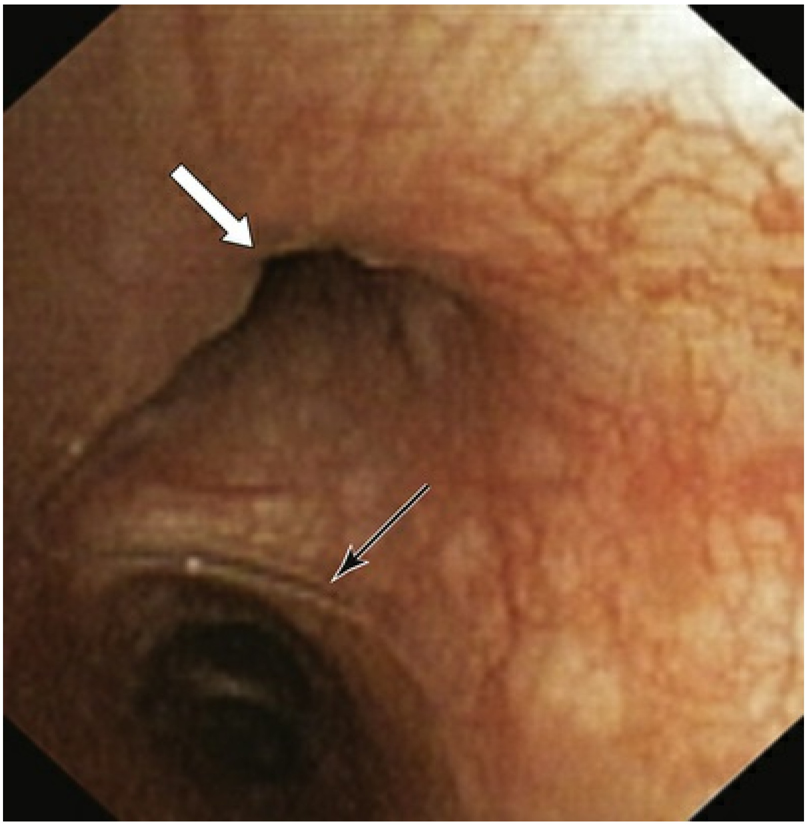

**FIG. 26.7** Bronchoscopic picture from a child with bronchiectasis. Airway mucosal abnormality in child with bronchiectasis depicting mucosa erythema and irregularity, muscularis ridging *(black arrow)*, and bronchomalacia (*white arrow*, right middle lobe).

## Assessment of Severity

### Pulmonary Function.

In children, spirometry is insensitive in detecting early structural lung damage in children with bronchiectasis, both in CF[164] and non-CF.[52] Spirometric values may be normal, but when a spirometric abnormality is present[52,165]; it is usually obstructive in the earlier stages and becomes a mixed obstructive and restrictive process when bronchiectasis is more severe. Although $FEV_1$ correlates with chest HRCT abnormalities in some populations, it is not a sensitive measure, especially if bronchiectasis is localized.[52,165] $FEV_1$ can also be normal, as in CF, in the early stages of disease even when radiological bronchiectasis was present.[164] However, when bronchiectasis is diffuse, spirometric abnormalities, although insensitive to disease activity, reflect disease severity.[164] Other pulmonary function test abnormalities described are a high residual volume, lower aerobic capacity, and lower maximal ventilation at maximal exercise.[166] Effort limitation during cardiopulmonary exercise testing does not relate to HRCT scores.[167]

There are limited data on how bronchiectasis alters respiratory system resistance or reactance measured by forced oscillatory techniques (FOT). In children, indices obtained from impulse oscillometry during exacerbations were not significantly different from the stable state.[168] In the stable state, resistance at 5 Hz was poorly sensitive to lung disease.[168] In children with CF, indices from FOT are not only insensitive at baseline but also cannot detect lung progression over 12 months.[169]

Another tool to assess severity of bronchiectasis is lung clearance index (LCI). The LCI reflects ventilation inhomogeneity in peripheral airways. Data in children with CF suggest that LCI changes occur early and before other physiological measurements when evaluating lung damage.[170] Among adults with stable non-CF bronchiectasis, the LCI negatively correlated with $FEV_1$ % predicted and was abnormal more often than FEV1.[171] However, a study involving 25 paired measurements of adults with non-CF bronchiectasis found that LCI was less sensitive than $FEV_1$ when evaluating improvement after treatment with intravenous antibiotics and physiotherapy for respiratory exacerbations.[170] While $FEV_1$ and vital capacity significantly improved, there was no significant change in LCI after intravenous antibiotics and physiotherapy.[170] The same study also undertook paired measurements in 25 adults with stable bronchiectasis and described that LCI indices were reproducible and, compared to controls, LCI was significantly higher.[170] There are no studies in children with non-CF bronchiectasis to know its sensitivity to early disease.

### Radiology.

There are at least eight radiographic scoring systems to assess severity of bronchiectasis using plain films. However, given the insensitivity of chest radiographs in detecting bronchiectasis, these scoring systems have been superseded by chest HRCT scoring systems described by Webb et al.,[97] Bhalla et al.,[172] and Reiff et al.[156] These chest HRCT scoring systems are based on composite scores of multiple radiological findings. Some systems utilize expiratory scans,[173] while others do not.[97] The Webb composite score[97] is a summation score of severity, extent, and features of emphysema and consolidation/atelectasis. The Bhalla score[172] comprises the sum of scores assigned to each of nine categories: severity of bronchiectasis, peribronchial thickening, extent of bronchiectasis, extent of mucus plugging, sacculations, generations of bronchi involved, number of bullae, emphysema, and collapse/consolidation. One study compared these three scoring systems in a group of 59 children with non-CF bronchiectasis.[52] The correlation between the scores ranged from 0.61 to 0.8 but none related to $FEV_1$ values. Magnetic resonance imaging (MRI) is an emerging technique for assessing bronchiectasis, but it is currently poorer than CT in evaluating airway diseases.[174,175]

### Other Markers.

A UK group developed the bronchiectasis severity index for adults[6] as a stratification tool for morbidity and mortality. The index includes features that are rare in children (e.g., $FEV_1$ of <30% predicted) and is thus not used in children.

The world of “omics” is blooming, but there currently are no studies relevant to clinical care in bronchiectasis. In children with CF, metabolomics using mass spectrometry have described possible biomarkers of BAL neutrophilic inflammation.[176] Techniques such as expired breath analysis and breath condensate measurements described almost two decades ago have not advanced in bronchiectasis.

## Assessment of Disease Progression

To date, there is little research on the most sensitive and appropriate method of assessing progression of bronchiectasis in children. Clinicians rely on frequency of respiratory exacerbations and on daily clinical symptoms, which may be perceived differently by children and their parents. There is no bronchiectasis severity score for children. QoL scores that are not specific for cough have been used in children with bronchiectasis, but to date, there is no pediatric bronchiectasis-specific QoL score.

The most sensitive objective assessment of early disease progression is based on HRCT changes, as these precede most pulmonary function changes.[52,165] However, repeated HRCT scans are not recommended purely for assessment of disease progression given the known risks of radiation in young children.[177] Other assessments of disease progression include chest radiographs which are insensitive, lung function, markers of neutrophilic airway inflammation, and possibly assessments of airway proteases. One small cross-sectional study showed significant correlations between HRCT severity scores and symptoms, $FEV_1$, sputum IL-8, and TNF-$\alpha$ levels (r values of 0.64, −0.68, 0.41 and 0.41, respectively).[53] However, there are no data relating these airway markers to imaging assessments longitudinally and disease progression.

## Assessment of Infection

Sputum sampling is the easiest method of obtaining an endobronchial microbiologic profile, but young children often do not expectorate sputum even when they have substantial lower airway secretions. Hence, in young children, assessment of lower airway microbiology requires bronchoscopy to obtain BAL and lower airway samples. BAL remains the gold standard, although the criteria for defining infection remains controversial.[11,178] Studies have generally used a threshold of bacterial growth of $\geq 10^4$ colony forming unit (cfu)/mL BAL to indicate infection.[11,179]

Other methods for identifying airway pathogens from children with bronchiectasis are oropharyngeal or nasopharyngeal swabs and induced sputum. In adults with bronchiectasis, sputum culture is generally reflective of lower airway organisms obtained by bronchoscopic catheter protected brushings.[180] One study on children with bronchiectasis described that the sensitivity and negative predictive value of nasopharyngeal cultures for individual respiratory bacterial pathogens, causing lower airway infection using BAL for comparison, ranged from 75% to 100%, and the specificity and positive predictive value were lower (32% to 72%).[72]

Common respiratory pathogens in children with bronchiectasis are *Streptococcus pneumoniae* and *H. influenzae nontype b*. Other organisms include *Moraxella catarhallis* and *Pseudomonas aeruginosa.* In pediatric bronchiectasis, the pathogen isolation rate from sputum or BAL is 53% to 67%.[58,109] Pseudomonas is commonly found in adults with severe bronchiectasis, but it is uncommon in children until adolescence or when bronchiectasis is severe.[58] In adults, a systematic review[181] found that persistent pseudomonas endobronchial infection was associated with increased disease severity measured radiographically, with spirometry, with death (threefold), and with more hospitalizations and poorer QoL; there are no such data in children. While nontuberculous mycobacteria and Aspergillus are commonly found in adults with bronchiectasis, they are rarely present in children with bronchiectasis.[58,72]

A number of children with bronchiectasis are persistently colonized with potential pathogenic microorganisms.[180] The largest study to report on microbiology in children with bronchiectasis was undertaken when they were clinically stable.[58] *H. influenzae* was identified in 32%, *S. pneumoniae* in 14%, *M. catarrhalis* in 8%, and *S. aureus* in 5% of BAL cultures.[58] *P. aeruginosa* was present in seven (6%) children of whom six had bronchiectasis involving multiple lobes, and five had other comorbidities.[58] The study also reported that respiratory viruses (principally respiratory syncytial virus and adenovirus) were present in 14 (12%) children; codetection of respiratory pathogens was found in more than half of those with positive microbiology results.[58] When the adenovirus was genotyped, almost all were type C, and the presence of adenovirus was significantly associated with bacterial coinfection with *H. influenzae, M. catarrhalis, or S. pneumoniae* (OR 3.27; 95% CI 1.38 to 7.75) and negatively associated with *S. aureus* infection ($P = .03$) in the BAL.[182] Studies on the microbiota (using bacterial 16S rRNA gene pyrosequencing) in children[9] and adults[183] with bronchiectasis have been reported. However, their impact on clinical management is yet to be defined. Nevertheless, one study that compared the microbiota of children and adults with bronchiectasis reported that the respiratory microbiota significantly differed from each other.[9]

Pulmonary exacerbations among children with non-CF bronchiectasis are often triggered by viruses and an increased density of known bacterial pathogens in sputum. The single prospective study in children that evaluated the point prevalence of viruses associated with exacerbations reported that respiratory viruses were detected during 37 of 77 (48%) exacerbations.[184] As the viruses reported included those commonly found in well children (rhinovirus [n = 20], enterovirus [n = 4] bocavirus [n = 4] coronavirus [n = 1]), it is possible that the percentage of true virus-associated triggers is lower. Classical respiratory viruses (adenoviruses, metapneumovirus, influenza, respiratory syncytial virus, parainfluenza [n = 3 each]) were found in only 15 (20%) exacerbations.[184]

## Assessment and Importance of Exacerbations

There is one published study that developed a standardized definition of exacerbation in children.[168] In 69 children over 900 child months, the study described validated major and minor criteria that can be used in the hospital or primary care setting. The major criteria were the presence of a wet cough and a cough severity score of ≥2 over 72 hours (area under the curve [AUC] of 0.85 [95% CI 0.79 to 0.92] and 0.84 [95% CI 0.77 to 0.91] respectively).[168] The minor criteria were change in sputum color, chest pain, dyspnea, hemoptysis and new chest signs on physical examination. The inclusion of investigations (investigatory criteria: elevated serum C-reactive protein, amyloid-A, or IL6) to the definition improved its specificity and positive predictive value.[168] Other infrequent features of importance are reduced exercise tolerance and energy.[185] Fever and hemoptysis are uncommon in exacerbations of bronchiectasis in the pediatric age group.[168,185]

Determinants of accelerated lung function decline in adults with bronchiectasis are frequency of hospitalized exacerbations, increased systemic inflammatory markers, and colonization with *P. aeruginosa*.[186] In one study of 52 children over a 3-year interval, the only significant predictor of $FEV_1$ decline was frequency of hospitalized exacerbations[79]; with each exacerbation, the $FEV_1$ % predicted decreased by 1.95% adjusted for time.[79] It is likely that interventions that can reduce exacerbations prevent further lung dysfunction.[187] Also, exacerbations, particularly when recurrent, are one of the strongest predictors of poor QoL among adults with bronchiectasis.[188,189] A prospective study involving 93 Indigenous children in Alaska and Australia showed that factors associated with recurrent (≥2) exacerbations included age less than 3 years, respiratory-related hospitalization in the first year of life, and pneumonia or hospitalization for exacerbations in the year preceding enrollment.[1] The study also reported that with clinical care and time exacerbations occurred less frequently.[1]

Exacerbations should be treated such that at the end of treatment, there are improvements in cough character, general well-being, QoL indicators, and inflammatory markers with reduced sputum volume and purulence, decreased sputum bacterial load or pathogen clearance, and a return toward the patient's stable baseline state.[109,190]

## Management and Treatment Principles

As early as 1933, Roles and Todd emphasized the importance of early diagnosis and treatment in reducing mortality associated with bronchiectasis.[36] Over the ensuing years, other authors such as Field[74] emphasized the importance of treatment "Even with simple medical treatment, the progress of most cases can be arrested…."[74] In bronchiectasis secondary to CF and primary ciliary dyskinesia, aggressive management of infections with antimicrobials, regular use of airway clearance methods, attention to nutrition, coupled with vigilant monitoring of long-term clinical trends, and proactive care led to improved survival and preservation of lung function.[191] CF produces a specific type of progressive bronchiectasis that differs from other forms of bronchiectasis with respect to mucus rheology, airway surface abnormalities, salt content, airway microbial pathogens, and extrapulmonary organ involvement. Although blind extrapolation of management used in CF to non-CF bronchiectasis can be harmful,[192] management of children with bronchiectasis should be arguably as intensive in children with idiopathic bronchiectasis to minimize acute exacerbations, daily symptoms, and functional limitations; thus improving the prognosis. Indeed, more recent data have provided evidence that intensive treatment of children who either have bronchiectasis or who are at risk of developing severe bronchiectasis prevents poor lung function in adulthood.[79,193] Even among children with serious underlying conditions, such as congenital immunodeficiencies and bronchiectasis, comprehensive regular care and surveillance programs have delayed decline in lung function over a period of a year.[194]

The aims of regular review include optimal postnatal lung growth, prevention of premature respiratory decline, maximal QoL, and prevention of complications due to bronchiectasis. Issues that require regular monitoring are listed in Box 26.3. Ideally, a team approach with incorporation of allied health expertise (nursing, physiotherapy, nutritionist, social work) should be used, as this model has been shown to improve health outcomes for several chronic diseases.[195] Evidence-based guidelines of management of bronchiectasis in children have been published since 2002 and subsequently updated,[190] and adults have been included.[196] An umbrella Cochrane review on the interventions for bronchiectasis has been published.[197]

**Box 26.3**

### Management Issues for Regular Review

1. Accurate diagnoses of underlying etiology and conditions that aggravate bronchiectasis
2. Philosophy of antibiotics use (maintenance, intermittent, regular hospitalizations)
3. Airway pathogens and drug-sensitivity profiles
4. Effectiveness of mucociliary clearance techniques
5. Nutritional state and support
6. Psychosocial support and adherence issues
7. Pattern and frequency of acute respiratory exacerbations
8. Presence of comorbid conditions
9. Education and promotion of self-management
10. Preventive measures (environment assessment, vaccines)
11. Indications for surgical resection of bronchiectatic regions

12. Complications related to bronchiectasis (e.g., hemoptysis, lung abscess, pulmonary hypertension, sleep disorders, reactive airway disease)
13. Review of new therapies and therapeutic strategies as they emerge, for example, macrolide use for antiinflammatory, antisecretagogue effects.

## Antimicrobials

Antimicrobial treatment is a key intervention in the management of patients with bronchiectasis.[109] In stable adult patients, there was a direct relationship between bacterial load and the risk of both subsequent and severe exacerbations (ORs of 1.2, 95% CI 1.1 to 1.3 and 1.1, 95% CI 1.0 to 1.2; respectively).[112] However, there are few published randomized controlled treatment trials on childhood bronchiectasis and none that focus on acute exacerbations.[198] Brief antimicrobial interventions significantly improve the inflammatory profile in the airways,[199,200] and blood,[199,200] sputum production, cough frequency, and QoL measures.[200,201] Use of antimicrobials for bronchiectasis was recently summarized.[109]

In general, the type of antimicrobial should target known pathogens and the route dependent on the severity of the illness and response to previous treatments.[109,190] Ideally, a sputum culture should be obtained prior to initiating antibiotics. Oral antibiotics are usually prescribed initially, but more severe episodes, or failure to improve with oral agents, require intravenous antibiotics combined with more intensive airway clearance techniques. Although robust evidence is lacking, a course of antibiotics for 14 days has been recommended by respiratory specialists.[112,190]

Comprehensive care programs for bronchiectasis have used both intermittent antibiotics to treat exacerbations and chronic or maintenance antibiotic treatment strategies. The use of maintenance antimicrobials may be suitable in selected situations where frequent exacerbations are likely to occur. Old studies in adults demonstrated that regular use of macrolides and trimethoprim reduced pulmonary inflammation, infective exacerbations and improved lung function.[202,203] A pediatric randomized controlled trial (RCT) involving 25 children (12 weeks of roxithromycin 4 mg/kg twice a day or placebo) also described a significant improvement in sputum markers and of airway responsiveness in the roxithromycin group, but improvements in $FEV_1$ were not observed in either group.[204] More recent studies in adults and children have confirmed these findings.[205] However, many questions remain, such as when should maintenance antibiotics be started and in whom, what is the optimal duration (studies suggest effects are evident only after 3 months), whether macrolides are the best choice of maintenance treatment, and which macrolides to use. Other questions are the optimal type and dosing regimen (daily-to-weekly) and whether associated increases in *S. aureus* and other macrolide-resistant bacteria are harmful at individual or community levels.[206] The latest Cochrane review (children and adults included) consisted of 18 studies whereby the meta-analysis showed that in patients with at least one exacerbation, the use of maintenance antibiotics (for >4 weeks) significantly reduced exacerbations compared to placebo or usual care with a reduction of 275 exacerbations per 1000.[205] Hospitalization was also reduced (50 fewer hospitalizations per 1000 people treated).[205] There was a threefold higher likelihood of antibiotic resistance in the group using maintenance antibiotics.[205] However, in the sole RCT that reported on use of antibiotics for conditions other than respiratory exacerbations, those in the antibiotic arm required 50% less other antibiotics (Incidence Rate Ratio = 0.5, 95% CI 0.31 to 0.81).[80] The factors affecting the risk of development of resistance to long-term macrolide therapy are adherence (adherence ≥70% reduces risk OR 0.34, 95% CI 0.14 to 0.81 compared to <70%) and baseline macrolide resistance rate.[207] The majority of the long-term studies used macrolides that have antiinflammatory and antisecretagogue effects.[208]

## Antiinflammatory and Antioxidant Agents

In 18 children with CF and 15 children with idiopathic bronchiectasis, 6 months of beta-carotene supplementation reduced plasma levels of TNF-$\alpha$ and malondialdehyde, a marker of lipid peroxidation,[209] but did not change clinical status. In adults with bronchiectasis, nonsteroidal antiinflammatory agents have a major effect on peripheral neutrophil function, significantly reducing neutrophil chemotaxis and fibronectin degradation by resting and stimulated neutrophils, but they had no effect on bacterial colonization of the airways or superoxide anion generation by neutrophils.[210] There are no studies on oral nonsteroidal antiinflammatory drugs (NSAIDs), but a Cochrane review on inhaled NSAIDs found a single trial in CSLD.[211] In adults with bronchiectasis, Tamaoki et al. reported a significant reduction in sputum production over 14 days in the treatment group (4 days of inhaled indomethacin) compared to placebo and significant improvement in a dyspnea score.[212] There was no significant difference between groups in lung function or blood indices. Emerging drugs in development have been recently reviewed.[213]

## Antisecretagogues and Mucoactive Agents

Mucoactive agents enhance mucus clearance from the respiratory tract in conditions where mucus clearance is impaired.[104] Mucolytics reduce mucus crosslinking and viscosity by disruption of polymer networks in the secretions through severing disulfide bonds, depolymerizing mucopolysaccharides, liquefying proteins, and degrading DNA filaments and actin.[104] In adults, high doses of bromhexine (not available in some countries) used with antibiotics eased difficulty in expectoration and reduced sputum production.[197] Recombinant deoxyribonuclease (rhDNAse) is efficacious in CF but is contraindicated in non-CF bronchiectasis. In a double-blind, RCT, multicenter study for 24-weeks in 349 adults with bronchiectasis, those given rhDNAse had higher exacerbation and hospitalization rates and more rapid pulmonary decline (decrease in $FEV_1$ 3.6% in rhDNase group; 1.6% in placebo group).[192] Inhaled osmotic agents, such as 7% hypertonic saline and mannitol, improve airway clearance and lung function and reduce exacerbation frequency in people with CF but studies in adults with non-CF bronchiectasis show a benefit only in time to first exacerbation and QoL and not in exacerbation rates.[214] There are no studies in children and clinically selected children can be commenced on hypertonic saline. When used, pretreatment with a short-acting bronchodilator is recommended to avoid bronchospasm, which occurs in up to 30% of patients.

Antisecretagogues reduce airway mucus production and secretion. These agents include anticholinergic agents, macrolide antibiotics, and bromhexine. Fourteen-member-ring macrolides are antibiotics with antiinflammatory activities and their use is discussed in the antimicrobials section. There are no RCTs on anticholinergics in the treatment of acute or stable bronchiectasis. Some anticholinergic agents such as atropine and glycopyrrolate slow mucociliary transport and predispose to further mucus stasis. An uncontrolled trial of tiotroprium in adults with hypersecretory states, including bronchiectasis that was resistant to macrolides, reduced daily symptoms and improved QoL with short-term use,[215] but it is not currently recommended in children.

## Airway Clearance Methods

Although it is lacking a robust evidence-base,[216] airway clearance techniques (encompassing various types of chest physiotherapy) are recommended in children and adults.[190,196] Available studies suggest that airway clearance techniques are beneficial with improved QoL and exercise capacity and reduced cough and sputum volumes.[216] Thus daily chest physiotherapy is recommended in a form that maximizes potential benefit and minimizes burden of care. In the past, postural drainage was standard therapy for children with CSLD/bronchiectasis. However, this treatment may increase gastroesophageal reflux and possible aspiration.[217] Given the availability of multiple techniques for airway clearance and the lack of clear superiority of any one technique, specific choices should be individualized and pediatric-specific physiotherapist expertise sought. In addition, children with bronchiectasis should be encouraged to participate in exercise activities.

## Asthma Therapy

Asthma in children with bronchiectasis should be treated on its own merits. Inhaled corticosteroids (ICS), at best, have a modest benefit in those with severe CSLD/bronchiectasis and those with *P. aeruginosa*.[218] The Cochrane review (six studies in adults, no pediatric studies) found that in the short term (ICS for <6 months duration), adults on very high doses of ICS (2 g per day of budesonide equivalent) had significantly improved $FEV_1$, FVC, QoL, and sputum volume but no improvement in peak flow, exacerbations, cough, or wheeze when compared to adults in the control arm (no ICS). When only placebo-controlled studies were included in the review, there were no significant differences between groups in any of the outcomes examined (spirometry, clinical outcomes of exacerbation or sputum volume). A single study on medium-term (>6 months) outcomes showed no significant effect of inhaled steroids on any of the outcomes.[218] There is no published RCT on the use of ICS for children with CSLD/bronchiectasis.[218] One study reported that 12-week withdrawal of ICS resulted in a significant increase in bronchial hyperreactivity and decrease in neutrophil apoptosis but no change in the children's clinical parameters or sputum inflammatory markers.[219] This suggests that ICS have little role in the management of CSLD/bronchiectasis in children when asthma does not coexist.

Short- and long-acting β-2 agonists also have an indeterminate role in the management of bronchiectasis,[197] and their use must be individualized. Although the presence of asthma is associated with advanced bronchiectasis and a worse prognosis, treatment of asthma to alter long-term outcomes has not been studied. It may be that the asthmatic features associated with diffuse bronchiectasis reflect the disease itself rather than a concurrent condition. Whether published guidelines for asthma care pertain to patients with wheeze and airway hyperactivity is unclear. Increased cough in children with bronchiectasis should be initially treated as an exacerbation of bronchiectasis.

## Environmental Modification

*In utero* tobacco smoke exposure alters respiratory control and pulmonary development and physiology.[81,220] Tobacco smoke also skews the early immune function,[81] but its role in permanently altering local and systemic pulmonary immunity is unknown. Exposure to ETS increases susceptibility to respiratory infections, causes adverse respiratory health outcomes, and increases coughing illnesses.[81] Cessation of parental smoking reduces children's cough.[221] Behavioral counseling and motivational interviewing for smoking mothers reduces young children's ETS exposure in both reported and objective measures of ETS.[222]

Indoor wood smoke also increases acute respiratory infections, demonstrating an exposure-response effect.[223] Thus efforts to reduce smoke and biomass exposure including *in utero* exposure and children's exposure in the home must be maximized. There is low to moderate quality evidence that repairing houses decreases respiratory tract infections.[224]

## Prevention: Vaccines

Vaccination as per national schedules is recommended. Many of the diseases described as causing bronchiectasis (e.g., pertussis and measles) are now controlled in developed countries. Vaccinations for prevention of influenza are recommended despite the lack of evidence specific for bronchiectasis.[225,226] While there is no specific evidence for influenza vaccine in those with CSLD/bronchiectasis,[225] indirect evidence suggests that annual influenza vaccinations reduce morbidity, mortality, and health care cost in “at risk” groups.[227] For pneumococcal vaccination, limited evidence supports the use of the 23-valent pneumococcal vaccine in reducing acute infective exacerbations.[226] 23-valent pneumococcal vaccine is recommended for high-risk children, including those with bronchiectasis.[228,229] Current evidence support revaccination, although the frequency of revaccination is controversial.[228] A recent study found that vaccination with the pneumococcal 10-serotype with *H. influenzae* protein D conjugate vaccine was associated with improvements in NTHi-specific cell-mediated and humoral immune responses in children with CSLD.[230] While this is promising, further confirmatory data are required.

## Surgical Considerations

Surgery is considered most often when bronchiectasis is focal and medical therapy has failed. Surgery is very rarely undertaken now in affluent countries but is still a common intervention in less affluent countries.[231] Perioperative mortality for lobectomy and pneumonectomy has fallen dramatically. In a retrospective series of 109 children (mean age 7.6 years, range 1 to 15.5), 36% had minor postoperative complications (transient atelectasis in 26%, air leak 6%) and one child died within the 30-day postoperative period. Of the 83 children with an average follow-up period of 667 days, 76% showed improvement of clinical symptoms. This is similar to several reviews of surgical therapy for bronchiectasis; the compiled group of adult and pediatric patients experienced 1% mortality (6/597) and an operative complication rate of 8.5% (51/597).[232,233] Complications included empyema, bronchopulmonary fistula, hypotension, and bleeding, but surgical treatment of bronchiectasis was more effective in patients with localized disease.[233] Appearance of new bronchiectasis following surgical management has been described.[52,234] Indications for surgical intervention are controversial, and data from the 1940 to 1950's cannot be applied given the major advances in antibiotics, airway clearance techniques, and nutrition supplementation, and socioeconomic standards among underserved populations. Our suggested indications for surgical intervention are outlined in Box 26.4. Although lung transplantation has been reported widely for patients with CF, this option has only been used for adults with end-stage non-CF bronchiectasis,[235] and outcomes following lung transplantation in children without CF have not been reported.

**Box 26.4**

## Indications and Contraindications for Lobectomy

### Indications

1. Poor control of symptoms (purulent sputum, frequent exacerbations) despite optimal medical therapy
2. Poor growth despite optimal medical therapy
3. Severe and recurrent hemoptysis uncontrolled by bronchial artery embolization

### Relative Indications

1. Localized disease with moderate persistent symptoms

### Contraindications

1. Widespread bronchiectasis
2. Young child (<6 years)
3. Minimally symptomatic disease

### Social Determinants and Health Care

Finally, health cannot be isolated from social, economic, environmental, and educational issues. Health and health behaviors are closely linked to socioeconomic factors,[236,237] and increased poverty, with its associated consequences such as poor housing and poor water supply, is an independent risk factor for increased respiratory infections and associated mortality.[237] To effectively reduce the morbidity and mortality from CSLD and bronchiectasis in children, a multifaceted approach encompassing good clinical care and public health concerns bears consideration. Although it is beyond the scope of this article to address this important issue, future work must focus on the public health issues predisposing to childhood bronchiectasis if the disparity between developed and developing countries is to be reduced.

Delivery of chronic disease programs requires comprehensive and highly skilled culturally competent primary health care. Education of primary health providers should ideally focus on identifying children for appropriate referral and high quality local management. Initial assessment requires specialist expertise, and specialist evaluation is recommended to confirm diagnosis, investigate etiology, assess baseline severity, and develop a management plan. Similar to other chronic illnesses, individualized and multidisciplinary case management operating within an interprofessional framework is optimal. Similarly, deterioration should prompt early referral for specialist care. In addition, those with moderate or severe disease are best managed by a multidisciplinary team approach.

## Prognosis

Given the heterogeneity of etiological factors and host responses, regional severity, and distribution of bronchiectasis, it is not surprising that the prognosis is varied, ranging from mild respiratory morbidity to death from airway obstruction, pulmonary infection, and respiratory failure with hypercapnia. There are cases where bronchiectasis resolves radiographically with treatment.[22] However, these children remain at risk of developing bronchiectasis and should be monitored regularly for reemergence of symptoms and obstructive lung disease. More often, bronchiectasis persists on HRCT but becomes less severe clinically with fewer infectious exacerbations and less cough evident later in childhood. In a series of 46 children with HRCT–documented bronchiectasis, a third improved, a third remained symptomatic but stable, and a third worsened while receiving medical therapy[56] Both Field[131] and Landau et al.[238] reported reductions in exacerbations during the second and third decade of life despite persistence of bronchiectasis radiographically. What happens in the following decades is inferred from case series of adults with bronchiectasis, many of whom had onset of respiratory problems, if not bronchiectasis in childhood. However, these series do not depict the era of minimal symptoms that occur at adolescence and anecdotally reappear at age 35 to 40 years old.

There are three published studies (all retrospective) on longitudinal $FEV_1$ changes in children with non-CF bronchiectasis studied over variable intervals with varying results.[79,239,240] A British study (n = 59 over 2 years, n = 31 over 4 years) found that lung function improves with intensive treatment but does not necessary normalize.[239] Likewise, an Australian study (n = 52 over 3 years, n = 25 over 5 years)[79] found that lung function and anthropometric parameters remain stable over a 3- to 5-year follow-up period once appropriate therapy is instituted, and those with low function at diagnosis ($FEV_1$ % predicted <80%) improved with time.[79] In contrast, a New Zealand (NZ) study of 44 children over 4.5 years found that $FEV_1$ declined at 1.9% per annum.[240] The explanations for this contrast are speculative but likely include the different age groups, children from different ethnicities, and health care differences. Also, the NZ cohort had more extensive radiological disease with 89% bilateral disease (median of four diseased lobes, 95% with multilobar involvement). The Brisbane study found that the only significant predictor of $FEV_1$ decline (over 3 years) was frequency of exacerbations requiring hospitalization[79] The other two cohorts[239,240] did not examine for determinants of lung function decline.

Published data also suggest that delayed diagnosis is associated with poorer outcomes.[27,79] A large study of adults newly diagnosed with bronchiectasis showed that the decline in $FEV_1$ correlates with the duration of chronic wet cough,[37] the most common symptom of bronchiectasis.[241] For each additional year of productive cough, $FEV_1$% predicted declined by 0.51% in nonsmokers.[37] Adults with bronchiectasis who were symptomatic from childhood have much poorer lung function and worse chest CT scan scores than those with adult-onset symptoms.[37] In the Brisbane longitudinal study, children diagnosed earlier and hence managed earlier were significantly younger and had better long-term spirometry and growth parameters.[79] $FEV_1$% predicted decreased by 1.64% points for each year increase in age at diagnosis, but this was statistically nonsignificant.[79]

When bronchiectasis worsens, it may become increasingly saccular within a local lung region (see Figs. 26.2 and 26.3). Alternatively, bronchiectasis can extend to additional airways, either due to endobronchial spread of infection or evolution of disease at multiple airway sites. The frequency with which bronchiectasis extends to new lung regions varies with different series, from 2% to 35%.[242,243] Local progression of disease rather than extension to new areas is likely more common.

The most severe cases of bronchiectasis have diffuse airway involvement and are accompanied by airflow limitation, with or without concomitant airway hyperreactivity. The diagnosis of asthma in the context of an underlying lung disease may be difficult. Wheeze and asthma symptoms are common in people with CSLD/bronchiectasis, although reported prevalence varies from 11% to 46%.[57,244] While some studies describe asthma as a cause of bronchiectasis, it is more likely that wheezing illness is a secondary or coexistent condition or that asthma was initially misdiagnosed. Asthmalike symptoms in adults with bronchiectasis may be associated with an accelerated decline in lung function.[137] King reported that increased use of bronchodilators led to a trend of a greater $FEV_1$ decline over time in adults.[245] The NZ cohort found that while the presence of asthma was associated with lower $FEV_1$ at diagnosis, asthmatics had a slower rate of decline over the 5-year follow-up.[240]

Unfavorable prognostic factors for patients with bronchiectasis include presence of asthma, bilateral lung involvement,[131,246] saccular bronchiectasis,[246] frequency of exacerbations, and presence of *P. aeruginosa* in the airways.[181] The advent of better antibiotics, inhaled antibiotics, long-term oxygen therapy, and improved nutrition has improved prognosis. Cor pulmonale and right heart failure are now uncommon complications of advanced bronchiectasis in children. In one series, echocardiography in 50 children with bronchiectasis found only one child with pulmonary hypertension.[52] In addition, chronic lung infection and inflammation are independent risk factors for developing cardiovascular disease in adults.[247]

# Protracted Bacterial Bronchitis

## Epidemiology and Disease Burden

Prior to a diagnosis of PBB, most children with a chronic wet cough received multiple medications and consulted several health physicians.[34,248] An Australian multicenter study found 70% of 138 children with PBB had received asthma medications, and 76% had seen greater than five doctors previously because of persistent cough.[249] However, these findings were also similar to children with a chronic cough from other causes.[249] QoL scores of children with PBB were similar to children with cough due to asthma or bronchiectasis presenting to pediatric pulmonologists.[249,250] Importantly, QoL scores normalized once the cough resolved.[251] While the prevalence of PBB cases in the community clinics is unknown, studies from specialist clinics (pediatrics and/or pediatric pulmonology) from Australia[23,34] and Turkey[252,253] found PBB to be among the top three diagnoses in children with chronic cough, with the prevalence ranging from 6% to 42%.[11]

## Pathology and Pathogenesis

## Microbiology

In the first description of PBB,[23] BAL cultures grew the common respiratory bacterial pathogens, *S. pneumoniae, H. influenza,* and *M. catarrhalis* (Fig. 26.8). Subsequent studies confirmed this finding, although one retrospective study also identified *S. aureus* (11 of 50 children),[254] but quantitative bacteriology was not performed, making interpretation difficult. One study examined the presence of respiratory viruses in children with PBB.[255] This study reported rates of 39% for viruses detected by polymerase chain reaction (PCR) in the BAL fluid from 104 PBB cases compared to 9% of 49 other chronic respiratory disease controls (OR = 6.3, 95% CI 2.1 to 19.1). The most common virus identified was adenovirus (AdV),[255] which upon genotyping, belonged predominantly to AdV species C.[182]

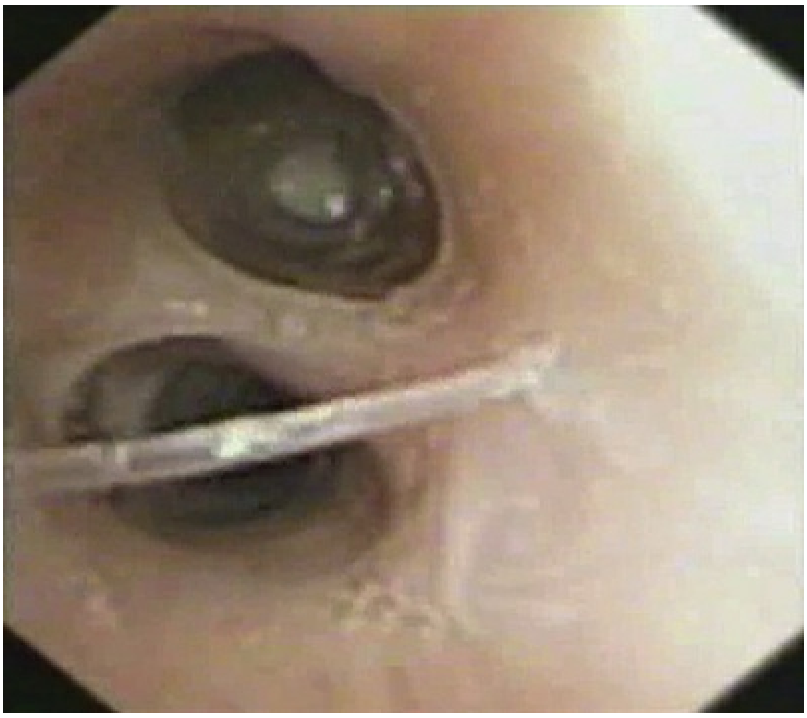

**FIG. 26.8** Bronchoscopic picture from a child with protracted bacterial bronchitis. The picture shows a strand of mucus just proximal to the left lower lobe bronchus and prominent secretions in the left lingula bronchus. The bronchoscopic appearances in children with protracted bacterial bronchitis are similar to those seen in mild bronchiectasis. The bronchoalveolar lavage from this child cultured *Haemophilus influenzae*

and *Streptococcus pneumoniae,* both at a density of greater than $10^5$ cfu/mL. Polymerase chain reaction for respiratory viruses (influenza A and B, RSV, parainfluenza 1-2, adenovirus, human metapneumovirus), Mycoplasma and Chlamydia were negative.

The presence and role of biofilms in the BAL of children with PBB have not been studied, but their presence has been speculated.[11] The microbiota of the lungs of children with PBB has been examined in a single cross-sectional study.[9] One-way analysis of variance showed the Shannon-Weiner index (a measure of species diversity) of the lower airway microbiota in children with PBB, and bronchiectasis were similar and statistically higher (i.e., richer) than in CF. The lung microbiota in children were significantly different from those observed in adults with CF and bronchiectasis, suggesting that chronic airway infections begin similarly with defective airway clearance of otherwise normal airway microbiota. Over time with antibiotic treatment and perhaps the effects of the underlying disease, the microbiota in these disease groups progressively diverge.[11,182]

## Immunity and Inflammation.

Studies on immunity in children with PBB[11] reported the following features: (1) absence of an overt systemic immunodeficiency (normal serum IgA, IgM, IgG, and IgE levels), (2) robust responses to protein (tetanus) and conjugated protein-polysaccharide *(H. influenzae type b)* vaccines,[255] and (3) upregulated innate immunity (e.g., elevated TLR-2, TLR-4, human β-defensin 2 [hBD2], and mannose-binding lectin [MBL][125]). A small BAL-based study described significantly decreased ability of alveolar macrophages to phagocytose apoptotic bronchial cells and NTHi in children with PBB (n = 13) compared to controls (n = 13).[122] For both types of impaired phagocytosis, the values in children with PBB were intermediate to those with bronchiectasis and controls (median phagocytosis of NTHi: bronchiectasis = 13.7% [IQR 11% to 16%], PBB = 16% [11 to 16], controls = 19.0% [13 to 21]; and median efferocytosis values were 14.1% [10 to 16], 16.2% [14 to 17] and 18.1 [16 to 21], respectively).[122]

BAL from children with PBB typically shows intense airway neutrophilia (median 40% to 44%).Whether this is a pathologically disproportionate response to infection is unknown.[11] There are also marked proinflammatory mediator responses (increased IL-8, MMP-9, and IL-1β) that correlate with BAL neutrophil percentages.[256,257] Median BAL levels of IL-8 and MMP-9 in children with PBB were 5- to 19-fold higher than controls and children whose cough resolved without treatment.[256] Children with PBB had significantly higher BAL fluid levels of IL-1β, α-defensin, IL-1 pathway members and CXCR2 gene and protein expression than non-PBB disease controls.[257] IL-1β levels correlated with duration and severity of cough,[257] and with elevated expression of α-defensins 1 to 3 in PBB cases. In those with recurrent PBB (>3 in the next 12 months), gene expression of the IL-1β signaling molecules pellino-1 and IL-1 receptor associated kinase (IRAK)-2 (in BAL at initial bronchoscopy) were significantly higher than those without recurrent PBB, suggesting this pathway's involvement in recurrence.[257] Thus, "PBB is characterized by increased IL-1β pathway activation. IL-1β and related mediators were associated with BAL neutrophils, cough symptoms, and disease recurrence, providing insight into PBB pathogenesis."[257]

### Large Airway Lesions.

While some clinicians believe TBM causes chronic ineffective cough, it is as likely that the airway malacia predisposes individuals to prolonged, inefficient airway clearance and hence increases risk of infection. Since the cough resolves once the underlying infection is treated, this suggests malacia has a limited causative role.[23] Nevertheless, TBM is found commonly in children with PBB.[23,258] This association may be primary (airway malacia predisposes to PBB through reduced efficiency in airway clearance) or secondary (malacia developing because of intense airway inflammation and infection).[161,259] One retrospective study reported TBM was present in 52/74 (74%) children with PBB.[258] However, a prospective study involving 104 children with PBB found that these airway abnormalities were no more common in children with PBB than in those undergoing bronchoscopy for other respiratory indications at a tertiary pediatric hospital (68% vs. 53%, respectively).[255] However, it has been shown in a prospective study that, children with TBM (c.f. controls) have a higher frequency of respiratory infections and symptoms.[260,261]

# Clinical Features

## Symptoms and Signs

Children with PBB have a chronic wet cough but otherwise typically appear well with an absence of recurrent nasal or ear disease. They have normal growth and development, and lack signs of underlying CSLD. The prevalence of atopic features (eczema, systemic and airway eosinophilia, elevated IgE, or positive radioallergosorbent test) is similar to children without PBB.[255] While many parents report previous "ever wheeze" (41% to 81%),[255,262] wheeze on auscultation confirmed by doctors is unusual. Occasionally, a "rattly chest" can be palpated and crackles are heard.

## Imaging and Pulmonary Function Tests

The chest radiograph is normal or near-normal, showing only peribronchial changes.[12,249,263] When performed, both spirometry[249] and respiratory system reactance and resistance measured by FOT are normal.[11] Laboratory findings, when undertaken, show absence of serum neutrophilia or systemic inflammation (CRP and erythrocyte sedimentation rate [ESR] normal).

# Diagnosis and Differential Diagnosis

## Defining Protracted Bacterial Bronchitis

When PBB was first described in 2006,[23] its existence as a distinct diagnostic entity was controversial. However, it is becoming recognized increasingly and is now incorporated into all national pediatric chronic cough guidelines.[11] It is also forms part of the European pediatric respiratory training curriculum.[264] PBB was first defined *a priori* and was based on clinical experience before being applied to a subgroup of children in a prospective study evaluating the etiology of chronic cough.[23] The diagnostic criteria were (1) history of chronic wet cough, (2) positive BAL cultures for respiratory bacterial pathogens at densities ≥$10^4$ cfu/mL without serologic or PCR assay evidence of infection by either *Bordatella pertussis* or *Mycoplasma pneumoniae,* and (3) cough resolution after a 2-week course of oral antibiotics (amoxicillin-clavulanate).[23] The consideration of feasibility in day-to-day clinical practice and further research has resulted in definitions (Box 26.5) based on recurrence and clinical setting.[11] Each criteria has been validated.[11] However, uncertainties remain and include (1) diagnosis can only be determined after a trial of therapy, (2) lack of research data on an optimal length of antibiotics, and (3) uncertainty of the diagnostic threshold for determining lower airway infection.[11]

**Box 26.5**

## Diagnostic Criteria for Protracted Bacterial Bronchitis

1. Original microbiologic-based case definition[23] (also termed PBB-micro)
    a. Presence of chronic wet cough (>4 weeks)
    b. Lower airway infection (recognized respiratory bacterial pathogens growing in sputum or BAL at density of a single bacterial specifies ≥$10^4$ colony-forming units/mL)
    c. Cough resolved following a 2-week course of an appropriate oral antibiotic (usually amoxicillin-clavulanate)
2. Modified clinical-based case definition[265] (also termed PBB-clinical)
    a. Presence of chronic wet cough (>4 weeks)
    b. Absence of symptoms or signs of other causes of wet or productive cough[a]
    c. Cough resolved following a 2-week course of an appropriate oral antibiotic (usually amoxicillin-clavulanate)
3. PBB-extended = PBB-clinical or PBB-micro, but cough resolves only after 4 weeks of antibiotics.

4. Recurrent PBB = recurrent episodes (>3 per year) of PBB.

*BAL*, Bronchoalveolar lavage; *PBB*, protracted bacterial bronchitis.

---

[a] Specific cough pointers[265–267] are: chest pain, history suggestive of inhaled foreign body, dyspnea, exertional dyspnea, hemoptysis, failure to thrive, feeding difficulties (including choking/vomiting), cardiac or neurodevelopmental abnormalities, recurrent sinopulmonary infections, immunodeficiency, epidemiological risk factors for exposure to tuberculosis, signs of respiratory distress, digital clubbing, chest wall deformity, auscultatory crackles, chest radiographic changes (other than perihilar changes), lung function abnormalities.

Chang AB, Upham JW, Masters IB, et al. State of the art. Protracted bacterial bronchitis: the last decade and the road ahead. *Pediatr Pulmonol.* 2016;51:225-242.

Differentiation between acute bronchitis and PBB is because acute bronchitis cough usually resolves within 2 to 4 weeks. Difficulties arise when recurrent and acute bronchitis episodes overlap, especially during the "respiratory virus" season.[11] Furthermore, PBB can coexist with other illnesses, including asthma, and recurrent episodes need to be differentiated from bronchiectasis when chronic wet cough does not respond to greater than 4 weeks of oral antibiotics.[268] Among 105 children with persistent cough despite at least 4 weeks of antibiotics, 88 (83.8%) had bronchiectasis; of the 24 children whose cough resolved after antibiotics, only six (25.0%) received this diagnosis (adjusted OR 20.9; 95% CI 5.4 to 81.8).[268]

## Differential Diagnosis

There are many causes of chronic wet cough in children, and further investigation to elucidate the cause is necessary when the child does not respond to antibiotics and/or has other clinical features, for example, coughing with feeds.[11,179] These are addressed elsewhere in this textbook.

Bronchitis is a component of many airway diseases. In the literal translation of the word, bronchitis refers to inflammation of the bronchus or bronchi. However, bronchitis has different major overlapping constructs based on duration (acute, subacute, chronic), inflammation type (neutrophilic, eosinophilic, lymphocytic, neurogenic), phenotype, or clinical syndromes (e.g., acute bronchitis, larygnotracheobronchitis, PBB, aspiration bronchitis). A diagnostic entity may have varying types of airway inflammation (Table 26.4). For example, acute viral bronchitis is associated with both lymphocytic and neutrophilic inflammation. Although the types of airway inflammation do not distinguish etiology of the bronchitis in children, it provides support for the diagnosis. Cough usually occurs when bronchitis is present.

## Table 26.4

## Dominant Type of Airway Cellularity in Selected Childhood Diseases With Bronchitis

| Inflammation Type | Examples of Disease | Other Key Airway Makers |
|---|---|---|
| Neutrophilic | Acute viral infection[269] | Soluble intercellular adhesion molecule-1 |
| | Bronchiectasis[116,128] | Elevated IL-8, neutrophil elastase, TNF-α, IL-1β |
| | Cystic fibrosis[270] | Elevated IL-8, neutrophil elastase, proteases |
| | Protracted bacterial bronchitis[11,257] | Elevated IL-8, MMP-9, IL-1β and related mediators that reflect IL-1β pathway activation |
| | Chronic lung disease of prematurity[271] | Proinflammatory cytokines and chemokines |
| | Severe bronchiolitis[272,273] | Myeloperoxidase, CD11b<br>RSV proteins and mRNA transcripts in severe RSV bronchiolitis |
| | Bronchiolitis obliterans[274] | Elevated IL-6, IL-8, TNF-α, IL-1β |
| | Aspiration lung disease[275] | Index of lipid-laden macrophages (nonspecific marker), amylase, pepsin (still needs validation) |
| Eosinophilic | Atopic asthma[276] | Elevated nitric oxide in steroid naive |
| | Helminth infections[111] e.g., toxocara and strongyloides | |
| | Allergic bronchopulmonary aspergillosis[277] | Neutrophilic inflammation may also be present with elevated IL-8 and MMP-9 |
| | Hypersensitivity, eosinophilic pneumonia[278] | |
| Lymphocytic | Acute viral infection[269] | Soluble intercellular adhesion molecule-1 |
| | Bronchiolitis obliterans[279,274] | CD8+T lymphocytes |
| | Autoimmune disease*[280] | |
| Neurogenic | Post RSV infection[281] | substance P, nerve growth factor |
| | Cough with gastroesophageal reflux[282] | Calcitonin G-related peptide |

Chronic (>4 weeks) wet cough in children signifies the persistence of increased airway secretion production or decreased airway clearance in the large airways.[283] The greater the amount of secretions seen at bronchoscopy, the higher the likelihood of bacterial infection and intense neutrophilia in the airways.[284] Clinicians need to be cognizant that recognition of wet cough is dependent on the clinical setting, and it is also likely age dependent. It is easier to detect a wet cough in young children, while older children may have a productive cough but may have a dry cough when asked to cough. Parents and clinicians have varying ability to recognize cough quality. In Australia, Brisbane-based parents were more accurate in determining the type of cough (compared to pulmonologists [kappa = 0.75, 95% CI 0.58 to 0.93] and flexible bronchoscopy findings),[283] whereas Indigenous caregivers were less accurate.[285]

## Management and Treatment

There is high-quality evidence that in children with greater than 4 weeks' duration of wet or productive cough, the use of appropriate antibiotics improves cough resolution.[179] In PBB, the child's cough resolves only after a 2-week course of appropriate antibiotics, in contrast to shorter durations of treatment.[23,286] Meta-analyses of three RCTs that used 10 to 14 days of antibiotics for chronic wet cough found that the number needed to treat (for benefit by end of study) was 3 (95% CI 2.0 to 4.3) Although the British Thoracic Society (BTS) cough guidelines[287] suggest all children with PBB should receive 4 to 6 weeks of antibiotics, there is no prospectively derived evidence for this. While some children with PBB may need longer antibiotic treatment, we advocate the shorter 2-week course initially.[11]

## Prognosis

The rate and risk factors of PBB recurrence are likely dependent on the sampling frame and definition. Factors in those severe enough to need to bronchoscopy and BAL sampling are probably different from those enrolled from the community. The sole prospective study to date was undertaken in 106 children with PBB followed for a median of 25 months (IQR 24 to 28).[288] Their median age at bronchoscopy was 23 months (IQR 14 to 53). At the 24-month follow-up, children with PBB were more likely to be coughing compared with controls (44% vs. 12% of respective cohort, $P = .005$) and to have had parent-reported wheeze in the preceding 12 months (58% vs. 16%, $P = .001$). By the end of the study, 66 (62%) of those with PBB had experienced recurrent episodes (>3 per year) and 13 (12%) had bronchiectasis diagnosed by chest CT scans.[288] The major independent risk factors for bronchiectasis were *H. influenzae* (mainly NTHi) lower airway infection and having ≥2 siblings. *H. influenzae* infection conferred greater than six times higher risk of bronchiectasis than a *H. influenzae* negative state (hazard ratio = 6.8, 95% CI 1.5 to 30.8).[288]

## Acknowledgment

We are grateful to Dr. Rosalyn Singleton for her expert comments and critique on the chapter published in the 7th edition of this textbook.

# Influenza

*Suchitra Rao MBBS, Ann-Christine Nyquist MD, MSPH, Paul C. Stillwell MD*

## Introduction

Influenza viruses are enveloped ribonucleic acid (RNA) viruses and belong to the family Orthomyxoviridae. There are three virus types within this family: influenza A, B, and C. Influenza A and B viruses are the types that predominantly infect humans, and A viruses are responsible for pandemic outbreaks of influenza and annual epidemics.[1]

The virus contains three important envelope glycoproteins: hemagglutinin (HA), neuraminidase (NA), and matrix proteins (M1 and M2). HA is the viral attachment protein responsible for entry of the virus into cells; it is an important surface antigen to which virus-neutralizing antibodies are directed. NA is an enzyme whose main function is to facilitate the cell-to-cell spread of virus; it is the target for the antiviral drugs zanamivir and oseltamivir. Antibody against HA is very protective against infection and illness, and antibody against NA can reduce illness severity. The matrix protein 2 (M2) is a structural protein linking the viral envelope with the virus core and is integral to the infectivity of the influenza virion. Influenza viruses have a segmented genome, containing eight strands of RNA. This property enables gene reassortment to occur among different subtypes of influenza, allowing new subtypes to form. Variation in the structure of HA and NA between influenza virions is the basis of the subtype H and N classification nomenclature (e.g. influenza A H1N1) (Fig. 27.1).

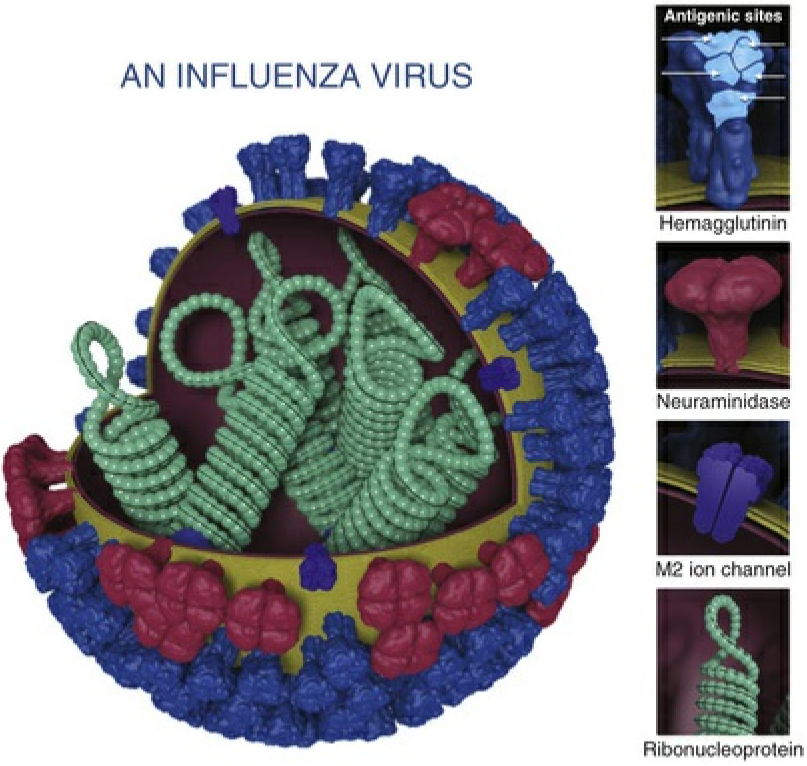

**FIG. 27.1** Graphic representation of an influenza virion showing its structure and important components. *RNP,* Ribonucleoprotein. (From http://www.cdc.gov/flu/images.htm.)

Influenza viruses have developed ways to evade the body's immune response using an antigenic variation known as antigenic *shift* and *drift.* Antigenic shift is seen only with influenza A viruses and results from the replacement of HA (or occasionally NA) with novel subtypes from other nonhuman influenza viruses. Introduction of a new HA into human viruses results in a pandemic, or worldwide epidemic, with the potential to cause millions of influenza-related deaths.[2]

Antigenic drift results from the accumulation of mutations within the antibody-binding sites in HA, NA, or both. These mutations prevent antibodies against previous strains from being effective against the current strain, enabling spread throughout a partially immune population. Antigenic drift occurs in both influenza A and B viruses.[3] Antigenic shift and drift must be taken into account when strains are being considered for inclusion in annual influenza vaccines.

# Epidemiology

Human-to-human transmission of influenza occurs through small-particle aerosols or droplets, which enter the environment from an infected individual. The virus then binds to epithelial cells of the upper and lower respiratory tract. The incubation period from exposure to illness averages 2–3 days but can be as rapid as 18 hours or as long as 5 or more days. Healthy adults will shed influenza virus for 3–7 days, and young children may shed for 10 days or longer with generally higher viral titers.

Influenza occurs each year in winter through early spring and is associated with significant morbidity and mortality in certain high-risk populations (Table 27.1). In the United States up to 36,000 deaths per year are attributable to influenza, with people above 65 years of age accounting for more than 90% of deaths. Influenza is responsible for 5%–15% of upper respiratory tract infections in children.[4–6]

## Table 27.1

### Individuals at High Risk for Influenza Complications

| |
|---|
| Hospitalized |
| Severe, complicated, or progressive illness |
| Children aged <2 years[a] |
| Individuals <19 years receiving long-term aspirin therapy |
| Adults aged ≥65 years |
| People of all ages with:<br>chronic pulmonary (including asthma), cardiovascular, renal, hepatic, metabolic (including diabetes), hematologic, neurologic (including seizure disorders) conditions; intellectual disability (mental retardation), moderate to severe developmental delay, and neurodevelopmental conditions |
| People with immunosuppression |
| Pregnant or recently postpartum women |
| American Indians/Alaska Natives |
| People who are morbidly obese (body mass index ≥40) |
| Residents of nursing homes or chronic care facilities |

[a] Although all children below 5 years of age are considered at higher risk for complications from influenza, the highest risk is for those younger than 2 years, with the highest hospitalization and death rates among infants younger than 6 months.

Healthy children aged 6–23 months are at substantially increased risk of influenza-related hospitalizations, and children aged 24–59 months remain at increased risk of influenza-related clinic and emergency department visits and hospitalizations but less so than younger children.

## Pathology/Pathogenesis

Influenza virus infection begins with the attachment of viral HA to terminal sialic acids on the surface of target host cells. In the lungs, the target cells of the influenza virus are typically ciliated columnar epithelial or alveolar epithelial cells (AECs), with each HA subtype displaying a unique tropism. Attachment of the influenza virus triggers receptor-mediated endocytosis by host cells and thus entry into the cell. To effectively release influenza RNA into the cytosol, viral M2 forms ion channels in the viral envelope. Liberated viral RNA then travels to the nucleus of the infected cell, where messenger RNA (mRNA) and viral RNA are synthesized. Assembly and budding of daughter virions occurs at the cell surface, where NA facilitates virion release by cleavage of sialic acid attachments to viral HA. Without this cleavage, influenza virions aggregate at the cell surface and are not released, which is the mechanism by which NA inhibitors are effective.

Ultimately, viral infection leads to apoptosis of the infected epithelial cells, which denudes the airways, resulting in acute tracheobronchitis.[7–10] When type I AECs are damaged, the tight junctions of the alveolar capillary membrane allow a transudate of fluid and proteins to enter the alveolar spaces, producing acute alveolar damage with the potential of progressing to acute respiratory distress syndrome (ARDS).[11,12] Viral HA and M2 also inhibit the resorption of alveolar fluid by the epithelial sodium channel, further promoting alveolar edema. Influenza infection and resultant cytokine induction can also activate the endothelial pole of the alveolar capillary barrier, facilitating neutrophil influx and further disruption of barrier function.[11]

The host immune response to influenza infection is complex and redundant, incorporating both innate and adaptive processes (see Chapter 8 for details of innate and adaptive immune responses).[8–10,13] In response to infections, activated macrophages and neutrophils work to eliminate viral particles and damaged or apoptotic epithelial cells. Although this is a key element in viral elimination and the recovery of epithelial integrity, the inflammatory by-products—such as myeloperoxidase, neutrophil elastases, and increased nitric oxide synthase—may cause further injury to the airway.[8,9] Increased risk of secondary bacterial infection may be due to delayed epithelial healing after influenza infection, excessive interferon gamma production, and type I interferons.[8,9]

The majority of systemic symptoms observed in acute influenza infection are attributable to the cytokines produced and released during the host immune response. Viremia is uncommon in an immunocompetent host. Similarly, dysfunction in nonrespiratory organs—such as myocarditis, encephalopathy, encephalitis, and rhabdomyolysis—is not usually associated with viral infection in those tissues.[9]

Viral infections can also stimulate the Th2 arm of the immune system by producing thymic stromal lymphopoietin (TSLP), IL-25, and IL-33. TSLP stimulates dendritic cells to induce Th2 cells and predisposes the host to allergic airway inflammation and asthma. IL-25 and IL-33 stimulate type 2 cytokine–producing innate lymphoid cells (ILC-2) to synthesize IL-5 and IL-13, which are promoters of eosinophilic inflammation, excessive mucus secretion, and bronchial hyperresponsiveness. This may explain, in part, how acute influenza infection exacerbates asthma and potentiates a subsequent asthma phenotype.[14,15]

# Clinical Features

## Symptoms

There is great overlap in the symptomatology of influenza and other respiratory pathogens. The influenza syndrome usually has a sudden onset, associated with fever, headache, cough, sore throat, myalgia, nasal congestion, weakness, and loss of appetite.[16,17] In a retrospective study of adolescents and young adults with influenza-like illness, the best predictors of influenza infections were cough and fever, with a positive predictive value of 79%.[18] Young children, however, have a less classic presentation compared with adults and tend to have higher fevers, less prominent respiratory symptoms, and more gastrointestinal symptoms such as abdominal pain, vomiting, diarrhea, and decreased appetite.[16,19,20] Influenza infection is also an important cause of febrile seizures.[21]

Lower respiratory tract manifestations in young children are virtually indistinguishable from those due to other viral infections. Influenza, similar to other respiratory viruses, may cause bronchiolitis, interstitial pneumonia, laryngotracheitis (croup), bronchitis, exacerbations of asthma, wheezing, and pneumonia.[22] Extrapulmonary manifestations include myocarditis, hepatitis, encephalitis, myositis, renal insufficiency, Guillain-Barré syndrome, rhabdomyolysis, and multiorgan system failure.[23–28]

## Physical Findings

Findings on examination include tachypnea, conjunctival erythema, nasal injection, edema, nasal discharge, and cervical adenopathy. Rash is an uncommon manifestation of influenza, but when it occurs it is usually a generalized maculopapular rash sparing the palms and soles. Other rashes associated with influenza infection have been characterized as petechial, macular, papular, reticular, or purpuric; they can be localized and pruritic or nonpruritic.[29–34]

## Radiographic Findings

The chest radiographic features of influenza pneumonia are indistinguishable from those of pneumonia caused by other organisms.[35,36] The most common radiographic findings are bilateral, symmetric, perihilar, and peribronchial opacities, but focal opacities and asymmetric disease may also occur (Fig. 27.2).[36] Lymph node enlargement can occur, but pleural effusions are rare. The nonspecific findings make it challenging to differentiate viral from bacterial pneumonia based on the radiographic appearance alone. Younger children with influenza pneumonia may have bilateral patchy opacities that probably reflect the retention of mucus.[35] Progression of the pneumonia can lead to diffuse airspace disease with an ARDS picture and acute respiratory failure.

Complete resolution to a normal chest radiograph should be expected following mild disease.

## Complications

Children with chronic lung disease, asthma, airway disease, cardiovascular disease, neuromuscular disease, and immunocompromised states are at highest risk of complicated influenza infection (see Table 27.1).[37] Severe influenza infection can present with bilateral pulmonary infiltrates and hypoxemia, leading to ARDS and death.[11,38–40] In particular, the 2009 H1N1 pandemic influenza virus was associated with higher rates of life-threatening lower respiratory tract illness, including ARDS, which was thought to be due to an increased predilection to infection of ciliated epithelial cells of the lower respiratory tract.[41–43] Pneumonia and secondary bacterial infection is a common cause of hospitalization from influenza.[44] Although *Streptococcus pneumoniae* is the most common pathogen identified, *Staphylococcus aureus* is a commonly associated copathogen. Methicillin-resistant *S. aureus* (MRSA) coinfections with influenza are increasingly being identified and are a risk factor for mortality in previously healthy children and adolescents.[45] Clinical features that support a bacterial superinfection among children with influenza include secondary fever after a period of defervescence, focal findings on pulmonary auscultation, lobar consolidation on chest imaging, and new onset of respiratory compromise occurring several days after initial symptoms.[46]

## Diagnosis and Differential Diagnosis

Testing for influenza is recommended if positive or negative results will influence clinical management or clinical practice for other patients. Testing should be considered, regardless of immunization status, during the influenza season among children with fever and acute onset of respiratory signs and symptoms, and those with acute exacerbations of underlying chronic lung disease. Infants and young children with fever and no other signs and symptoms, hospitalized children with acute respiratory symptoms who develop an acute febrile respiratory illness, and severely ill children with fever or hypothermia should also be tested. Testing should occur at any time of the year for children who are epidemiologically linked to an influenza outbreak (e.g., household and close contacts of people with suspected influenza, returned travelers from countries where influenza viruses may be circulating, participants in international mass gatherings, and cruise ship passengers).[47] Testing 5 days or more beyond illness onset may result in false-negative test results because of decreased viral shedding; this occurs in particular among older children.

Testing modalities available include influenza-specific reverse transcription polymerase chain reaction (RT-PCR), multiplex respiratory pathogen PCR, direct fluorescent antibody (DFA) tests, and rapid influenza antigen tests. RT-PCR is the most accurate testing modality for influenza; it is useful for differentiating between influenza types and subtypes and is significantly more sensitive than rapid influenza antigen detection tests (>95% vs. 10%–70%, respectively). Rapid antigen tests have less sensitivity and specificity than RT-PCR tests. A meta-analysis of children demonstrated sensitivity of 64.6% for influenza A and 52.2% for influenza B.[48] These and other studies indicate that rapid antigen tests are not reliable during periods of low influenza activity. Immunofluorescent antibody testing can distinguish between influenza A or B and other respiratory viruses. However, the test performance is dependent on the quality of the respiratory specimen and expertise of the laboratory.

Viral culture is usually unhelpful in the clinical setting because results are not available until 48–72 hours later. However, it is helpful for the confirmation of screening results, surveillance, and research. Serologic testing is also not helpful in the clinical setting because acute and convalescent (obtained 10 days later) sera are required for diagnosis. Testing platforms include hemagglutination-inhibition, enzyme-linked immunosorbent assays (ELISA) and complement fixation assays. A fourfold rise or greater in antibody titers between acute and convalescent specimens confirms the diagnosis of influenza.

The differential diagnosis of influenza infection is listed in Table 27.2.[22]

### Table 27.2

### Differential Diagnosis of Influenza Infection

| Upper Respiratory Infection | Lower Respiratory Tract Infection | Exacerbations of Wheezing/Asthma |
|---|---|---|
| Rhinovirus | hMPV | RSV |
| hMPV | Adenovirus | hMPV |
| Adenovirus | RSV | Rhinovirus |
| RSV | PIV | Adenovirus |
| PIV | Coronaviruses | PIV |
| Coronaviruses | *Chlamydophila pneumoniae* | Coronaviruses |
| Enteroviruses | *Mycoplasma pneumoniae* | *Chlamydophila pneumoniae* |
| | Bocavirus | *Mycoplasma pneumoniae* |
| | *Streptococcus pneumoniae* | Bocavirus |
| | *Staphylococcus aureus* | |
| | *Haemophilus influenzae* | |
| | *Streptococcus pyogenes* | |

*hMPV*, Human metapneumovirus; *PIV*, parainfluenza virus; *RSV*, respiratory syncytial virus.

# Management and Treatment

## Treatment

Clinical trials and observational data show that early antiviral treatment can shorten the duration of fever, influenza symptoms, and hospitalization; it may also reduce the risk of complications from influenza (e.g., otitis media in young children, pneumonia, respiratory failure, and death).[49–54] Clinical benefit is greatest when antiviral treatment is administered early, especially within 48 hours of influenza illness onset.[49,55,56] Treatment should not wait for laboratory confirmation of influenza but should be started as soon as possible when clinically indicated.

Antiviral treatment is recommended regardless of the day of illness for any patient with confirmed or suspected influenza who is hospitalized; has severe, complicated, or progressive illness; or is an outpatient who is at higher risk for influenza complications based on age or underlying medical conditions. Clinical judgment—based on the patient's disease severity and progression, age, underlying medical conditions, likelihood of influenza, and time since onset of symptoms—is important in making decisions regarding antiviral treatment for high-risk outpatients. Antiviral treatment may be considered for any outpatient with confirmed or suspected influenza who is otherwise healthy if treatment can be initiated within 48 hours of illness onset.

Neuraminidase inhibitors (NAIs) oseltamivir and zanamivir are the antiviral medications still recommended for the treatment and chemoprophylaxis of influenza A and influenza B virus infections owing to near universal susceptibility. They inhibit the viral NA enzyme that helps progeny escape from infected cells. NAIs may also have efficacy against the novel influenza viruses. Oseltamivir is given orally for 5 days with dose adjustments required for renal impairment and weight (Table 27.3). The most common side effects of oseltamivir are nausea and/or vomiting. Transient neuropsychiatric events (self-injury or delirium) have been reported, mainly among Japanese adolescents and adults.[57] Zanamivir is a dry powder administered via oral inhalation. It is not FDA-approved for the treatment of children under 7 years of age. The dose is two breath-activated inhalations twice daily for 5 days. The prophylactic dose is two inhalations once daily for children 5 years of age and older. It is not recommended for children with underlying airway disease including asthma owing to lack of safety and efficacy data in these individuals. Serious adverse events include bronchospasm and decline in lung function, most commonly seen in patients with underlying airway disease. (If zanamivir is used in patients with underlying airway disease, they should be instructed to have a short-acting bronchodilator available.) Allergic reactions including rashes and oropharyngeal or facial edema have been reported. Side effects include diarrhea, nausea, sinusitis, rhinitis, nasal congestion, bronchitis, cough, headache, dizziness, and ear/nose/throat complaints. Peramivir is an intravenous NAI indicated for the treatment of acute, uncomplicated influenza in patients 18 years of age and older who have been symptomatic for no more than 2 days; it is given as a single 600-mg administration.

## Table 27.3

## Treatment and Prophylactic Dosing of Oseltamivir

| Age | Treatment Dose | Prophylactic Dose |
|---|---|---|
| 2 weeks–3 months[a] | 3 mg/kg per dose twice a day | Not recommended unless situation judged critical |
| Children 3–11 months[b] | 3 mg/kg per dose twice a day | 3 mg/kg per dose once daily |
| Children 1–12 years old and weighing | | |
| ≤15 kg | 30 mg/dose twice a day | 30 mg once daily |
| >15–23 kg | 45 mg/dose twice a day | 45 mg once daily |
| >23–40 kg | 60 mg/dose twice a day | 60 mg once daily |
| >40 kg | 75 mg/dose twice a day | 75 mg once daily |
| Children ≥13 years of age and adults | 75 mg/dose twice a day | 75 mg once daily |

[a] Although not part of the US Food and Drug Administration (FDA)-approved indications, use of oral oseltamivir for treatment of influenza in infants less than 14 days old and for chemoprophylaxis in infants 3 months to 1 year of age is recommended by the Centers for Disease Control and Prevention (CDC) and the American Academy of Pediatrics.

[b] The American Academy of Pediatrics recommended an oseltamivir treatment dose of 3.5 mg/kg orally twice daily for infants aged 9–11 months for the 2013–14 season on the basis of data indicating that a higher dose of 3.5 mg/kg was needed to achieve the protocol-defined targeted exposure for this cohort as defined in the Capability Acquisition and Sustainment (CASG) 114 study (Kimberlin, 2013).[68] It is unknown whether this higher dose will improve efficacy or prevent the development

of antiviral resistance. However, there is no evidence that the 3.5-mg/kg dose is harmful or causes more adverse events to infants in this age group.

Matrix protein inhibitors amantadine and rimantadine target the M2 protein and are potentially effective against only influenza A owing to the lack of a M1/M2 protein channel in influenza B viruses. These antiviral medications are not currently recommended for treatment or chemoprophylaxis since most circulating influenza A strains have developed resistance to them.[58–60]

Steroids have been proposed as an adjunctive therapy for influenza pneumonia; however, several studies failed to demonstrate clinical benefit in the treatment of patients with severe influenza infection. Furthermore, studies indicate an increase in overall mortality, increased incidence of hospital-acquired pneumonia, and longer duration of mechanical ventilation and ICU stay in patients treated with steroids.[61,62]

# Prevention

Routine annual influenza vaccination is recommended for all children 6 months of age and older. Ideally, vaccination should occur before the onset of influenza in the community and should be administered as soon as a vaccine supply is available. Vaccination should be continued as long as influenza viruses are circulating. Multiple different vaccine formulations are available, and some are licensed for specific age groups or are more appropriate for particular patient populations. Recommendations regarding influenza and vaccine dosing are updated by the CDC each year and are available via the Centers for Disease Control and Prevention (CDC) influenza website (http://www.cdc.gov/flu/); they are also published in the *Morbidity and Mortality Weekly Report* by the CDC.[63,64] Two formulations of vaccine are approved for children: inactivated influenza vaccine (IIV) and live-attenuated influenza vaccine (LAIV). LAIV is an intranasal vaccine and is offered solely in quadrivalent form. IIV is available in trivalent or quadrivalent formulations. The Centers for Disease Control and Prevention (CDC) has recommended that LAIV should not be used until further notice due to low vaccine effectiveness against influenza A during the 2013–2014 and 2015–2016 seasons. Recombinant influenza vaccine (RIV) is available for adults with egg allergy.

Children 6 months through 8 years of age receiving vaccine for the first time require two doses of vaccine at least a month apart. Influenza vaccine contraindications are provided in Table 27.4. Data demonstrate that IIV and LAIV[65] given in a single, age-appropriate dose is well tolerated by virtually all recipients who have egg allergy. Children with anaphylaxis to eggs may receive influenza vaccine by a health care provider who is familiar with the potential manifestations of egg allergy in a setting where anaphylaxis can be recognized and treated. Such children should be observed for at least 30 minutes for signs of a reaction after administration of each vaccine dose.

## Table 27.4

**Influenza Vaccine Contraindications and Precautions**

| Vaccine | Contraindications | Precautions |
|---|---|---|
| Inactivated influenza vaccine ($II_3$ or $II_4$)<br>Cell culture–based $IIV_3$<br>High-dose $IIV_3$ | Severe allergic reaction to any component of the vaccine, including egg protein, or after previous dose of any influenza vaccine. | Moderate to severe illness with or without fever; history of Guillain-Barré syndrome within 6 weeks of receipt of influenza vaccine. |
| Recombinant influenza Vaccine ($RIV_3$) | Severe allergic reaction to any component of the vaccine. | Moderate to severe illness with or without fever; history of Guillain-Barré syndrome within 6 weeks of receipt of influenza vaccine. |
| Live-attenuated influenza vaccine ($LAIV_4$)[a] | Severe allergic reaction to any component of the vaccine, including egg protein, or after previous dose of any influenza vaccine.<br>Concomitant use of aspirin or aspirin-containing medications in children and adolescents.<br>In addition, Advisory Committee on Immunization Practices recommends $LAIV_4$ not be used for pregnant women, immunosuppressed people, people with egg allergy, and children aged 2–4 years who have asthma or who have had a wheezing episode noted in the | Moderate to severe illness with or without fever.<br>History of Guillain-Barré syndrome within 6 |

| | | |
|---|---|---|
| | medical record within the past 12 months, or for whom parents report that a health care provider stated that they had wheezing or asthma within the last 12 months. | weeks of receipt of influenza vaccine.<br>Asthma in people 5 years of age and older.<br>Medical conditions that might predispose to higher risk for complications attributable to influenza. |

[a] LAIV should not be used until further notice due to low vaccine effectiveness against influenza A during the 2013–2014 and 2015–2016 seasons.

## Chemoprophylaxis

NAIs are 70%–90% effective in preventing influenza. Yet the CDC does not recommend widespread or routine use of chemoprophylaxis owing to the possibility that resistant viruses could emerge, thus limiting the usefulness of these medications for high-risk or severely ill people. Oseltamivir can be used for chemoprophylaxis of influenza among infants below 1 year of age when indicated, although, owing to limited data in this age group, children less than 3 months of age should not receive prophylaxis unless the situation is judged to be critical.

Chemoprophylaxis is not usually recommended if more than 48 hours have elapsed since the last exposure to an infected person. For effective prophylaxis, an antiviral medication must be taken each day for the duration of potential exposure to a person with influenza and continued for 7 days after the last known exposure. Postexposure prophylaxis should be considered for family members and close contacts of infected patients if they are at high risk of complications from influenza.

# Prognosis/Outcome

With or without antiviral treatment, most children have a full and uneventful recovery after an acute, uncomplicated influenza infection. Unfortunately, some will have a fatal outcome. Death from influenza is more frequent in children with comorbidities such as asthma or severe neurologic impairment and in those who develop ARDS.[66] A small proportion of children may develop asthma after experiencing an acute influenza infection, although asthma subsequent to infection seems to be more common with other viral lower respiratory tract infections such as RSV or human rhinovirus.[67]

## Introduction

In this era of rapid globalization and frequent travel, emerging viral infections have gained an immense potential to spread at an unprecedented speed and scale compared with the past. This poses a significant challenge to coordinated international efforts in global surveillance and infection control.

Significantly, respiratory viral infections, spread mostly via droplet transmission, are extremely contagious and have caused significant morbidity and mortality during outbreaks in the last decade. Molecular diagnostics via reverse transcriptase polymerase chain reaction (RT-PCR) have been key in the rapid diagnosis of most of these viral infections. However, a high index of suspicion and early institution of appropriate isolation measures remain as the mainstay in the control and containment of the spread of these viral infections. Although treatment for most of the viral infections remains supportive, efficacious antiviral agents against influenza infections exist.

The infections discussed in this chapter include those first described in the 2000s: Middle East respiratory syndrome coronavirus (MERS-CoV) and metapneumovirus and rhinovirus C as well as those that have been described in the past but have reemerged in the last decade in outbreaks resulting in significant morbidity and mortality, including adenovirus, influenza virus, and enterovirus D68 (EV-D68).

## Epidemiology

EV-D68 was first isolated in 1962 in California and had been rare with occasional reports of clusters. Since the late 2000s, EV-D68 has been increasingly reported in various parts of the world. In August 2014, the US Centers for Disease Control and Prevention (CDC) reported cases beginning in the Midwest, with more than 1000 cases reported in 49 states in 2014.[1]

## Etiology

EV-D68 is a single-stranded, nonenveloped RNA virus. It belongs to the genus *Enteroviruses* and family Picornaviridae. It is one of the five EV-D serotypes identified so far. It has virologic characteristics including the ability to bind to $\alpha$-2, 6-linked sialic acids that are present in the upper respiratory tract, which facilitate respiratory infections (Table 28.1).[2]

### Table 28.1

### Summary Table of Characteristics of Emerging Viral Respiratory Infections

| Virus | Mode of Transmission | Incubation Period | Clinical Features | Diagnosis[a] |
|---|---|---|---|---|
| Enterovirus D68 (EV-D68) | ▪ Droplet<br>▪ Fecal-oral<br>▪ Fomites | 1–5 days | ▪ Respiratory<br>▪ Rarely flaccid myelitis<br>▪ Predilection to atopic individuals | ▪ PCR<br>▪ Viral cultures<br>▪ (including serum) |
| MERS-CoV | ▪ Droplet | 2–14 days, median of 5 days | ▪ ARDS<br>▪ Myalgia<br>▪ Gastrointestinal<br>▪ Asymptomatic | ▪ RT-PCR (including stool specimens) |
| Human | ▪ Droplet | 4–6 days | ▪ Respiratory | ▪ RT-PCR |

| | | | | |
|---|---|---|---|---|
| metapneumovirus | ▪ Fomites | Shedding can last 1–2 weeks | ▪ Gastrointestinal<br>▪ Predisposes to severe bacterial infections | ▪ Immunofluorescer assay (IFA) |
| Rhinovirus C | ▪ Aerosol or droplet<br>▪ Fomites | 0.5–3 days | ▪ Respiratory<br>▪ Coinfection with bacterial infections common | ▪ RT-PCR |
| Adenovirus | ▪ Aerosol or droplet<br>▪ Fomites<br>▪ Fecal-oral | 2–14 days Shedding up to 2 years in stool | ▪ Pharyngoconjunctival fever<br>▪ Respiratory<br>▪ Gastrointestinal<br>▪ Renal-hematuria | ▪ DFA<br>▪ PCR (throat, sputu and rectal swabs; blood and stool in immunocomprom<br>▪ Serologic rise in antibody titers |

[a] Unless otherwise stated, samples were obtained from the nasopharynx or oropharynx.

[b] Off-label use.

*ARDS,* Acute respiratory distress syndrome; *ARF,* acute renal failure; *DFA,* direct fluorescent assay; *MERS-CoV,* Middle East respiratory syndrome coronavirus; *RT-PCR,* reverse transcriptase polymerase chain reaction.

## Pathology/Pathogenesis

The pathogenesis of EV-D68 has been studied in animal models. Schieble and colleagues noted that the Rhyne strain demonstrated a neurotropic virulence with paralysis of mice. However, despite the predominant respiratory symptoms seen in humans, no effective animal models have been established. Humans are at the moment the only known natural reservoirs of the disease.

## Clinical Features

The incubation period for EV-D68 is between 1–5 days, similar to many other viral respiratory infections, and the infectious period lasts from a day prior to symptom onset to about 5 days after onset. Spread of infection occurs by droplet transmission and through the fecal-oral route or indirect contact with contaminated surfaces, as with other enteroviruses.

## Symptoms

EV-D68 primarily causes acute respiratory symptoms, unlike other enteroviruses. Presenting symptoms range from mild upper respiratory symptoms such as rhinorrhea, sore throat, fever, and rash to severe pneumonia. Most reported cases were associated with difficulty breathing and wheezing, but this may affected by reporting bias.[3]

Patients can also present with aseptic meningitis or encephalitis. EV-D68 infection has been reported to have a predilection for patients with a personal or family history of atopy.[1] The respiratory symptoms have also been reported to be more severe in those with underlying respiratory illnesses such as asthma, often requiring intensive care treatment. Prior to virological diagnosis, many of these cases were often discharged with a diagnosis of asthma exacerbation.

During the outbreak in California and Colorado, a significant group of children was reported to have presented with acute flaccid myelitis, symptoms of sudden asymmetric limb weakness, facial weakness, ophthalmoplegia, or bulbar signs; they were found to be positive for EV-D68 in their nasopharyngeal swabs. However, the spectrum of neurologic disease associated with EV-D68 has not been fully characterized.

## Physical Findings

The physical findings for infected patients are similar to those associated with most respiratory viral infections and are not specific to the disease. However, a significant number of EV-D68 patients have been reported with wheezing as the main clinical feature. Patients with more severe EV-D68 respiratory infections present with tachypnea and retractions.[3] As already mentioned, neurologic symptoms including flaccid myelitis have also been associated with EV-D68 infections.

## Imaging, Pulmonary Function Tests, Laboratory Findings

Chest radiographs often demonstrate peribronchial thickening and infiltrates, often with areas of atelectasis.[4,5]

## Diagnosis and Differential Diagnosis

EV-D68 can be identified using molecular methods, polymerase chain reaction (PCR), or viral cultures of fluid samples from the nasopharynx, oropharynx, and serum. Most commercially available respiratory multiplex PCR assays may not be able to distinguish enteroviruses from rhinoviruses, so specific assays for EV-D68 may be needed to identify infections with EV-D68 if the clinical suspicion is high.

## Management and Treatment

Supportive care remains the mainstay of treatment. No specific treatment is currently available.[4] Pleconaril has not been shown to be effective for EV-D68 to date.

## Prevention

There are currently no available vaccines. Good hand hygiene and prompt diagnosis with subsequent isolation of cases is the main approach to containing the spread of these infections.

## Prognosis

Initial studies had suggested that patients with EV-D68 infection, compared with other pulmonary pathogens such as rhinoviruses or non EV-D68 enteroviruses, were more likely to have severe respiratory symptoms and to require hospitalization.[1] However, in a more recent retrospective analysis of the outbreak at the St. Louis Children's Hospital,[3] the cases analyzed have shown no significant difference in severity of illness in EV-D68 patients compared with those with other viral etiologies. This may have been due to ascertainment bias, as more severely affected children were tested and thus the case fatality rate appeared to be much higher than it probably really was. This has happened with a number of respiratory viruses, including influenza A H1N1 in 2009, when it was first recognized.

In most cases of EV-D68 infection, with supportive care recovery is expected over a few days. Fatalities have been associated with neurologic complications or occasionally cardiac events.[6,7]

# Middle East Respiratory Syndrome Coronavirus

## Epidemiology

First reported in April 2012 in Jordan,[8] MERS-CoV spread rapidly to the Middle East, including the Kingdom of Saudi Arabia (KSA), the United Arab Emirates (UAE), and Qatar. Subsequent imported cases were then reported in European countries including France, the United Kingdom, Italy, and Germany and in North Africa (Tunisia). After the 2012 outbreak, there were only sporadic cases and nosocomial outbreaks reported from the Middle East until 2015, when a large outbreak occurred in Korea and Guangdong (China) involving 184 cases and 33 deaths.[9] Since 2012, according to statistics from the World Health Organization (WHO), there have been 1365 laboratory-confirmed cases of MERS-CoV infection, including 487 related deaths.

## Etiology

MERS-CoV is an enveloped single-stranded RNA virus belonging to the family Coronaviridae. As with most coronaviruses, the reservoir of infection is thought to originate from animals. MERS-CoV is postulated to have originated from the dromedary camels within the Arabian Peninsula. Molecular isolation of several alphacoronaviruses and betacoronaviruses from bats in Saudi Arabia and other parts of the world has suggested the involvement of bats in human infection as well. The actual route of zoonotic transmission has not been clearly defined despite the publication of a large case-control study.[10]

## Pathology/Pathogenesis

The exact pathogenesis of MERS-CoV is being elucidated. Studies looking at ex vivo infected hepatoma cells demonstrate severe cytopathic effects.[11] Hocke and colleagues[12] have demonstrated, through spectral microscopy, significant MERS-CoV antigen expression in type I and II alveolar cells, ciliated bronchial epithelium, and unciliated cuboidal cells of terminal bronchioles as well as pulmonary vessel endothelial cells. Evidence of alveolar epithelial damage with detachment of type II alveolar epithelial cells and associated disruption of tight junctions, chromatin condensation, nuclear fragmentation, and membrane blebbing were seen on electron microscopy.[12] The receptor for MERS-CoV has been identified as dipeptidyl peptidase 4 (DPP4) (CD26), an exopeptidase, which has been demonstrated in cells on spectral microscopy.[11]

MERS-CoV infection causes significant host immune dysregulation with downregulation of genes involved in the antigen-presenting pathway, leading to subsequent impaired adaptive immune responses, possibly explaining the rapid progression of the illness and the high mortality rate.

## Clinical Features

Most of the MERS-CoV infections were spread via travel to or residence in countries near the Arabian Peninsula. Infection occurs via droplet transmission from patients to close contacts. The risk of person-to-person transmission is generally low, but superspreading events have been identified similar to the severe acute respiratory syndrome (SARS) coronavirus, in which single individuals have been associated with transmission to large numbers of others. The median incubation period for secondary cases of human-to-human transmission is about 5 days (range 2–14 days).[13]

## Symptoms

In adults, infection results in fever as well as upper and lower respiratory tract symptoms including cough and breathlessness, which can rapidly deteriorate to severe acute respiratory distress syndrome. Other symptoms of myalgia and gastrointestinal symptoms of diarrhea, vomiting, and abdominal pain were commonly present.[14] However, two case series from the Middle East[15,16] have reported that MERS-CoV infection ran a milder course in children, with the majority being asymptomatic carriers who were contacts of symptomatic adult cases. Severe respiratory symptoms occurred more commonly in those with existing comorbidities.

The reported patients' age range has been from below 1 year to 99 years of age, although children have formed a minority of cases. This may be due to limited exposure to animals or health care settings where most infections have occurred.

The respiratory symptoms in symptomatic cases are rapidly progressive, with the median time from onset of symptoms to hospitalization being about 4 days and from onset to intensive care admission for severe cases approximately 5 days. Complications include acute respiratory failure, acute respiratory distress syndrome, refractory hypoxemia, and extrapulmonary complications (ischemic hepatitis, septic shock, hypotension, acute renal failure). The median time from onset to death was about 12 days.[13]

## Physical Findings

Patients presenting with symptomatic MERS-CoV infection have mainly lower respiratory findings, including tachypnea, rhonchi, and retractions, although upper respiratory symptoms have been reported.

## Imaging, Pulmonary Function Tests, Laboratory Findings

Reported chest x-ray findings have included unilateral or bilateral patchy opacities, consolidation, interstitial infiltrates, and pleural effusions.[13]

## Diagnosis and Differential Diagnosis

Laboratory confirmation of active MERS-coV infection is based on real-time reverse transcription PCR (RT-PCR) detection of at least two specific genomic targets or a single positive target with sequencing of a second target.[17] Confirmation with nucleic acid sequencing may be required for epidemiologic investigation of the origin and spread of the disease. Specimen collection sites for RT-PCR include lower respiratory samples (bronchoalveolar lavage, tracheal, or sputum aspirates) and upper respiratory samples (nasopharyngeal and oropharyngeal swabs) as well as serum and stool specimens, although the highest yield has been from respiratory samples.[17]

Serologic testing by enzyme-linked immunosorbent assay (ELISA), immunofluorescence assay (IFA) or microneutralization assay is available for the detection of previous infection and is used mainly for surveillance purposes; it should not be used as a diagnostic tool as there is a risk of cross-reactivity with other coronaviruses.

A single negative result on a recommended specimen sent is sufficient to demonstrate no active MERS-CoV infection according to the definition of the US CDC. However, if the clinical suspicion remains, more samples should be sent, as false-negatives do occur.

Patients who have been diagnosed with MERS-CoV are considered clear of active infection and can be deisolated when two consecutive specimen tests are negative on RT-PCR.

Other infectious etiologies presenting similarly with acute, rapidly progressive respiratory distress syndrome include SARS and influenza virus (H5N1). Noninfective causes of acute respiratory distress syndrome (ARDS) should be considered as well. The epidemiologic history and a high index of clinical suspicion are critical.

## Management and Treatment

No specific antivirals have developed at this point, and the mainstay of treatment remains supportive care.

## Prevention

Currently no vaccine is available against MERS-CoV. Strict infection control measures, including standard, contact, and droplet precautions, with airborne precautions for aerosol-generating procedures, must be taken when care is being provided for suspected or confirmed cases. These have been shown to be effective in controlling nosocomial outbreaks in both the KSA and

South Korea. Continued vigilant epidemiologic surveillance, good hand hygiene, and cough etiquette remain the mainstays of prevention for areas not affected by outbreaks.

## Prognosis

The prognosis is guarded in symptomatic cases, especially in adults, with 3–4 of every 10 patients reported to have died. The number of children infected has been small, so it remains to be seen if the disease runs a more benign course in the pediatric age group. In the adult population, patients admitted to the intensive care unit had a 58% mortality rate at 90 days post admission.[18]

# Human Metapneumovirus

## Epidemiology

Human metapneumovirus (HMPV) was first isolated in pediatric patients with acute respiratory infections in the Netherlands in 2001.[19] Subsequent retrospective serologic studies demonstrated the presence of antibodies to HMPV in humans more than 50 years prior,[20] and the virus has since been found worldwide. HMPV accounts for up to 10% of viral respiratory tract infections, occurring commonly during the months of January through April in the United States.[21] However, a recent 7-year surveillance study in the United States reported that the HMPV season occurred after the respiratory syncytial virus (RSV) and influenza seasons.[22] Serologic studies have demonstrated that most children in Europe and North America have acquired a HMPV infection at least once by the age of 5 years.[20] Although this is a common childhood respiratory infection, immunity is believed to be transient, and HMPV infection is reported to contribute to acute respiratory illnesses in the elderly (above age 65) who have comorbid respiratory conditions such as asthma or chronic obstructive pulmonary disease or conditions resulting in an immunocompromised status. The overall rate of detection of HMPV was 6% among hospitalized children with respiratory studies.[21] Although there have been questions as to whether HMPV is truly a pathogen, asymptomatic carriage among children is estimated to be only 1%.[21]

## Etiology

HMPV is an enveloped single-stranded RNA virus and is a member of the Paramyxoviridae family, belonging to the subfamily Pneumovirinae under the genus *Metapneumovirus.* Two genotypes of HMPV exist, A and B; subgroups are based on the fusion (F) and attachment (G) surface glycoproteins.[20]

## Pathology/Pathogenesis

The pathogenesis of HMPV infection has been extensively studied in multiple animal models. Studies on young adult cotton rats inoculated with the virus demonstrate inflammation within and surrounding the bronchi and bronchioles with significant leukocytosis. The HMPV was found mostly on the apical surface of the columnar cells. In the same animal model, upregulation of mRNAs related to interferon gamma (IFN)-$\alpha$, CCL5, CCL2, CCL3 and interleukin (IL)-2 was demonstrated. Previous infection conferred partial protection in these rats, with lower viral loads within the respiratory tract and a neutralizing antibody response on subsequent infection.[23] However, long-term immunity seems unlikely given the incidence of disease in older adults.

## Clinical Features

HMPV infection is transmitted via close or direct contact with contaminated secretions; the incubation period of HMPV is estimated to be 4–6 days.[20] The duration of symptoms varies according to severity, but it is commonly less than a week. However, shedding of the virus in infected cases can last from 1 to 2 weeks after the acute illness, with viral RNA found in stools 5 days to 2 weeks after symptom initiation.[20] A large prospective surveillance study done by the US CDC on HMPV infection in children[21] found that infected children were mostly without comorbidities and most were younger than 5 years of age, with many infants less than 6 months of age. The annual rate of hospitalization associated with HPMV infection was similar to that of influenza virus (1 per 1000) but lower than that for RSV (3 per 1000).[19]

## Symptoms

Clinical infection with HMPV results in initial upper respiratory tract symptoms such as cough, rhinorrhea, and fever and can progress to lower respiratory tract symptoms of shortness of breath and wheezing. Sore throat, conjunctivitis, poor appetite, rash, and other gastrointestinal symptoms such as vomiting and diarrhea have been reported.[23–25] The diagnosis is often not made clinically. In a 2-year population-based prospective surveillance study, outpatient cases subsequently found to be positive for HMPV were discharged mostly with the diagnosis of viral illness and bronchiolitis, while inpatient cases were mostly discharged with a diagnosis of bronchiolitis, asthma, or pneumonia.[25] Although infections are usually mild and self-limiting, some studies suggest that HMPV infections can predispose to severe bacterial infections, which complicate the course of the disease.[20]

## Physical Findings

Clinical findings in infected cases are like those seen in other respiratory viral infections, although fever was less common in children with HMPV infections than those with influenza in one study.[25] However, findings of respiratory distress, tachypnea, and wheezing were more common in patients with HMPV infections than in those with influenza in the same study.

## Imaging, Pulmonary Function Tests, Laboratory Findings

Initial laboratory findings may reveal lymphopenia, neutropenia, and transaminitis,[26] or they may be completely normal. Chest x-ray findings for lower respiratory tract involvement in severe disease, especially in the immunocompromised, have demonstrated ground-glass opacities with parenchymal airspace consolidation, ill-defined nodular-like centrilobular opacities and bronchial wall thickening (Fig. 28.1).[26] Compared with RSV pneumonia, in one series HMPV pneumonia showed more asymmetrical findings.[26]

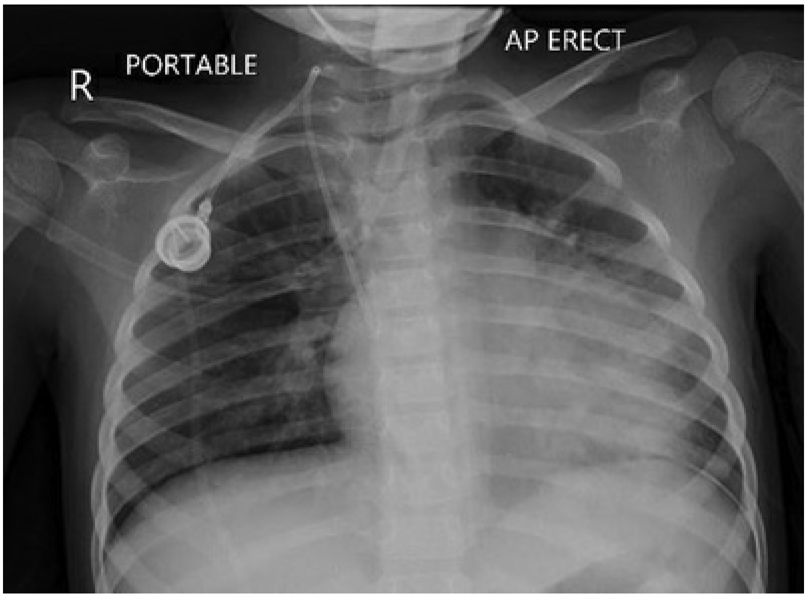

**FIG. 28.1** Chest x-ray in a 4-year-old patient with underlying acute lymphoblastic leukemia demonstrating left mid- to lower-zone consolidation consistent with a left-sided pneumonia. The bronchoalveolar lavage fluid was positive for human metapneumovirus on reverse transcriptase polymerase chain reaction testing.

## Diagnosis and Differential Diagnosis

Diagnostic tests for HMPV infection include various techniques of culture, the nucleic acid amplification test (NAAR), antigen detection and serologic testing. As culturing the virus is technically challenging owing to its slow growth and cytopathic effects in vitro, the most commonly used detection technique is via RT-PCR from nasopharyngeal or oropharyngeal samples. Direct IFA testing can be done in outbreak settings because of the shorter turnaround time, but IFA has a lower sensitivity.[20] Serologic testing has been used mainly for epidemiologic purposes.

Differential diagnoses for similar upper respiratory tract presentations would include other viral etiologies including RSV, influenza, parainfluenza, and adenovirus. In the immunocompromised host with lower respiratory tract signs, fungal etiologies would have to be considered as well.

## Management and Treatment

Treatment of HMPV infections, like that of other viral infections, is mainly supportive; however, there is much interest in developing therapeutic options. Ribavirin, a nucleoside inhibitor licensed for the treatment of RSV and hepatitis C infections, has demonstrated good in vitro and in vivo activity against HMPV in animal models. Antiviral fusion inhibitors are also currently being investigated.

Other promising treatment options include therapeutic antibodies. Following the successful introduction of monoclonal antibodies such as palivizumab for RSV infections, development of specific monoclonal antibodies against HMPV is ongoing. An example is MAb338, an antibody targeting the HMPV fusion protein, which has shown therapeutic potential in mouse models. Another example is the intranasally administered Human Fab DS7.[27] Standard intravenous immunoglobulin preparations have also been shown to inhibit replication of HMPV in vitro.[28]

RNA interference is a new approach to treating RNA viral infections by regulating gene expression through the silencing of specific mRNAs.[20] Two extremely efficient small interfering RNAs against HMPV have been identified by Deffrasnes and colleagues,[29] These are still in the investigation phase. Finally, Wyde and colleagues have investigated the antiviral properties of sulfated sialyl lipid and heparin and have found activity against HMPV in vitro.[30]

Although there has yet to be a randomized controlled trial on therapeutics in HMPV infections, in severe case, in uncontrolled studies a combination of oral and aerosolized ribavirin with polyclonal intravenous immunoglobulin had some effect.[20]

## Prevention

An effective vaccine against HMPV remains to be developed. Strategic targeting of the F and G surface proteins for both live attenuated and inactivated vaccine development is in progress.

Particularly challenging is the fact that natural infection confers only transient immunity and reinfections are common into adulthood. This raises questions about the protective effect of any future vaccine.

Infection control remains the mainstay of prevention, especially within the hospital. Droplet isolation of infected cases with lower respiratory tract symptoms should be implemented until symptom recovery.

## Prognosis

Although children infected with HMPV had a higher likelihood of supplemental oxygen use and were noted to have a longer intensive care unit (ICU) stay compared to respiratory infections from other causes, the rates of ICU admission and intubation remained similar to other respiratory infections. The lengths of stay in hospital were not significantly different[21] and fatal HMPV infections are rare.

# Rhinovirus C

## Epidemiology

Human Rhinovirus C (HRV-C) is the newest member of the HRV family, having been discovered only in 2006 after retrospective VP4 sequence analysis, done with respiratory samples from patients in Queensland and New York City, showed distinct clustering from known HRV-A and HRV-B species.[31] Shortly after being described, these rhinoviruses were quickly reported worldwide in countries including Africa, Asia, Australia, America, and Europe and are now estimated to contribute to greater than 5% of tested specimens, highlighting their importance as a cause of respiratory tract infections.[31] In Asia and the United States, HRV-C and HRV-A are the most prevalent of the three species. There appears to be a seasonality in HRV-C infections, with a peak incidence in the fall and winter, as well as the rainy season in tropical countries, but also occurring throughout the year.[31] HRV-C infection has a predilection for the young, with most infections occurring in children less than 5 years of age, especially those below the age of 36 months.[32] Part of the apparent rise in rhinovirus C infection may be due to improved virus detection methods that have led to an increase in its recognition as a cause of severe pneumonia in the elderly and the immunocompromised, specifically in pediatric oncology and patients who have undergone hematopoietic stem cell transplantation.

## Etiology

HRV-C is a positive-sense, single-stranded nonenveloped RNA virus from the Picornaviridae family. It is one of the three species of HRV based on phylogenetic sequence analysis and is distinctly distinguished from other previously described species (HRV-A and HRV-B) on the basis of genomic features.[33]

## Pathology/Pathogenesis

In healthy individuals, HRV-C infection mostly causes rhinosinusitis through a neutrophilic inflammatory response resulting in increased vascular permeability and mucus hypersecretion in the upper respiratory tract. Cough, though less common, is thought to be due to direct infection of the bronchi or irritation from the posterior pharyngeal drainage of secretions.[34] In patients with asthma or underlying lung disease, lower respiratory symptoms are more common. Despite the fact that rhinoviruses grow optimally at 33°C, which favors the upper respiratory tract, it is postulated that the warmer temperature in the lower respiratory tract is not an absolute barrier to replication. In many children with pneumonia, rhinoviruses have been isolated together with bacterial pathogens suggesting that HRV infection may lead to a predisposition to other respiratory pathogens.[34] This has been supported by studies demonstrating that human tracheal epithelial cells had increased adherence to *Streptococcus pneumoniae* when coinfected by HRV.[35] Other studies have also demonstrated that HRV-exposed macrophages had suboptimal responses to bacterial toll-like receptor agonists,[36] which may predispose to secondary bacterial infections in humans.

The true prevalence and pathogenic role of HRVs in the community has not been investigated in detail, and HRV has been found in lower airway fluids and cells of healthy volunteers.[37,38] Cohort studies, though, have shown high rates of HRV-C detection (up to 75%) in hospitalized children with lower respiratory illnesses.[39–41]

There are also increasing data linking wheezing secondary to HRV in early infancy with a higher risk of subsequent development of asthma compared with wheezing caused by other viruses. The Childhood Origins of Asthma (COAST) study showed that HRV-related wheezing in the first year of life led to a threefold risk of having asthma at 6 years. HRV wheezing in year 2 was associated with a more pronounced increase in asthma risk (odds ratio [OR] ~7), while HRV-related wheezing during year 3 of life was associated with an even dramatic (OR ~32) increase in asthma at school age.[42] A similar birth cohort study in Australia reported that HRV-related wheezing in infancy was associated with an increased asthma risk at 5 years.[43] The exact mechanisms by which HRV triggers or contributes to the inflammatory changes often seen in asthma is unclear, but it is suggested that it evolves from a combination of host susceptibility, other aeroallergen sensitization and the ability of HRV to activate proinflammatory and airway remodeling pathways.[44]

## Clinical Features

Symptoms of HRV-C infection typically occur after an incubation period of 12–72 hours. The disease is spread through aerosol or droplet transmission or direct person-to-person contact with contaminated secretions. Symptoms generally last 7–11 days.

## Symptoms

Symptoms of HRV-C infection in children include fever greater than 38°C, and both upper and lower respiratory symptoms of cough, wheezing and shortness of breath.[45] Infections commonly associated with HRV-C include acute upper respiratory tract infection, acute laryngitis, suppurative tonsillitis, otitis media, bronchitis, bronchiolitis, and bronchopneumonia. Although the clinical course is generally mild, HRV-C has been found to be more virulent than HRV-A[32] and can run a more severe course in immunocompromised hosts—for example, children with hematologic malignancies, hematopoietic stem cell transplant recipients, and those on long-term steroid use.

## Physical Findings

Common findings in HRV-C infection include upper respiratory tract signs of nasal congestion, cough, facial tenderness with sinus involvement, and inflammation of the tympanic membrane with otitis media. With lower respiratory tract involvement, symptoms such wheezing, cough, and dyspnea are common.

## Imaging, Pulmonary Function Tests, Laboratory Findings

Chest x-ray findings include increased haziness in the perihilar or lower zone regions (Fig. 28.2). Consolidative changes and pleural effusions were less commonly noted in children and more commonly found in adult patients.[31]

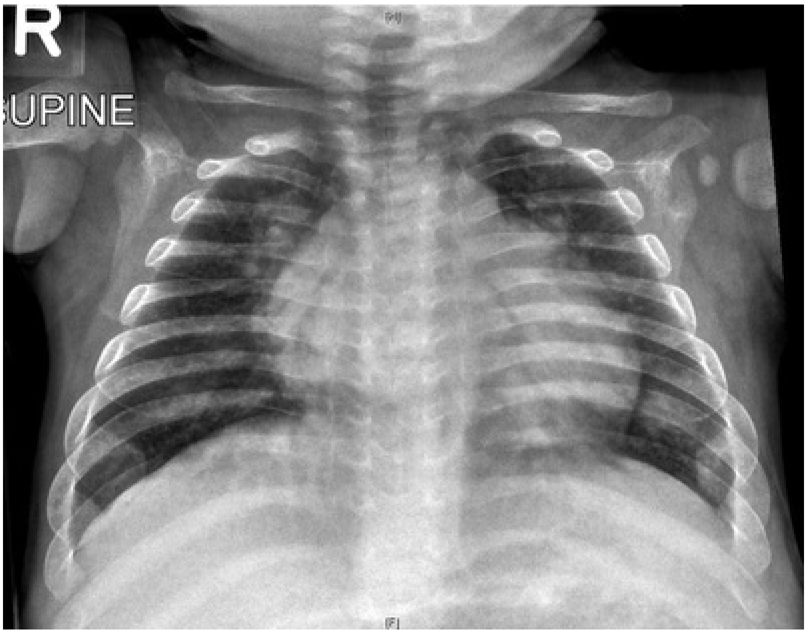

**FIG. 28.2** Chest x-ray of an 11-month-old infant with underlying decompensated liver disease and rhinovirus bronchiolitis. Bilateral perihilar infiltrates are demonstrated on this film.

## Diagnosis and Differential Diagnosis

Conventional methods of viral testing such as immunofluorescence have often missed the presence of HRV-C; hence the recommended gold standard for the diagnosis of HRV-C infection is molecular testing with RT-PCR from nasopharyngeal or oropharyngeal secretions. Coinfection with bacterial infections is common, and the degree of rhinovirus identification in asymptomatic individuals in the community is not known. Hence isolation of rhinovirus C in a single sample with lack of clinical improvement over time may require analysis for the presence of a concomitant bacterial pathogen.

## Management and Treatment

Similar to the other common viral upper respiratory tract pathogens already mentioned, treatment remains supportive and symptomatic. Pleconaril, an antiviral agent known to be effective against enterovirus and rhinovirus infections, seems to be an option for severe HRV-C infections. However, owing to the distinct genomic differences of HRV-C compared with the earlier discovered HRV-A, it is likely that HRV-C may be resistant to this drug.[46]

## Prevention

Despite the significant global burden of rhinovirus infection, no vaccine exists at this point because of antigenic heterogeneity between the greater than 150 rhinovirus strains.[47] Strict hand hygiene and droplet precautions for patients with upper respiratory tract symptoms remain the mainstays of prevention.

## Prognosis

Despite the initial reports of high mortality from rhinovirus C infections,[48–50] most cases are associated with a good prognosis. A recent study of hematology and oncology patients did not detect any deaths associated with HRV-C infection.[48] In a study from the

Philippines, although rhinoviruses were the most common pathogens identified in children hospitalized with pneumonia, there were no fatalities associated with HRV infections, unlike influenza A.[51]

# Adenovirus

## Epidemiology

Adenovirus has been recognized as a pathogen since its discovery in 1953. However, recent interest in this virus as an emerging or (more accurately) reemerging respiratory pathogen arose from continued small outbreaks worldwide in both the United States and Asia. These have affected infants and young children, with 90% of them below the age of 60 months.[52] Significantly, in Taiwan, there was a noted surge in cases in 2010–2011, triggering the establishment of a national surveillance system that found an acute rise of adenovirus-positive respiratory tract specimens from a baseline of 5.75% to a peak of 37.3% of all respiratory viruses isolated.[53] Outbreaks across Asia appear to be linked by molecular epidemiology, although the mode of international spread is not clear.[54]

## Etiology

Adenoviruses are icosahedral, nonenveloped, medium-sized, double-stranded DNA viruses with more than 50 immunologically distinct serotypes; they belong to the family Adenoviridae. The serotypes linked to epidemic keratoconjunctivitis include types 8, 19, 37, 53, and 54. Those that typically cause acute respiratory disease are types 3, 4, and 7, while the enteric adenoviruses in children are mainly types 40 and 41.[55]

Adenoviruses are known to be resistant to common disinfectants and can remain on surfaces and in the water of pools and lakes for long periods of time.[56]

## Transmission and Infection

Adenovirus is spread by droplet transmission of respiratory secretions or direct contact with infected secretions (respiratory, urine, stool, or ocular). The virus can also spread through water and via the fecal-oral route. Shedding of the virus in stools has been documented for up to 2 years after an infection, and shedding can occur in the urine as well. The virus can cause latent infection in lymphoid tissue such as the adenoidal and tonsillar tissues of the throat,[57] but the clinical significance of this is unclear.

## Clinical Features

The incubation period of adenoviral infections ranges from 2 to 14 days. Infection has been known to cause pharyngitis, adenoiditis, tonsillitis, otitis media, and keratoconjunctivitis, commonly known as pharyngoconjunctival fever. Lower respiratory tract involvement with pneumonia and bronchitis has also been seen. Adenoviral infections are also known to cause extrapulmonary manifestations, which are commonly seen as acute gastroenteritis and acute hemorrhagic cystitis, with some cases of hepatitis and rarely meningoencephalitis. Infection is particularly severe and prolonged in the immunocompromised, especially those who have undergone hematologic stem cell transplantation.

Certain serotypes, particularly 3, 7, and 21, have been reported to result in epidemics or fulminant events associated with long-term respiratory complications of bronchiolitis obliterans, bronchiectasis, and Swyer–James syndrome.[58,59] Bacterial coinfection in patients with adenoviral infections is noted to be rare, with a minimal role in the course of the disease in severe adenoviral infections.[53]

## Symptoms

The main symptoms of adenoviral infection include fever, cough, rhinorrhea, sore throat, and bilateral conjunctivitis, which can last from 3 to 5 days. Occasionally adenoviral infections cause prolonged fevers. Lower respiratory tract involvement is much less common. Extrapulmonary manifestations include diarrhea, abdominal pain, vomiting, and hematuria.

## Physical Findings

Pharyngoconjunctival fever typically manifests with bilateral conjunctivitis, an injected pharynx and tonsils with significant bilateral cervical lymphadenopathy. In adenoviral pneumonia, findings include significant hypoxia, wheezing, and features of pulmonary consolidation.

## Imaging, Pulmonary Function Tests, Laboratory Findings

Adenoviral infections can easily be confused with bacterial infections, as they are known to cause leukocytosis and neutrophilia on peripheral blood counts as well as elevated inflammatory markers.[59] Transaminitis is also often noted with adenoviral infections. Because of high fevers, which can be more prolonged than with other viral causes, children with adenoviral infections are often presumptively treated for bacterial infections, with blood and urine cultures, and antibiotics before the diagnosis is made.

For patients with lower respiratory tract involvement, chest x-ray findings typically show interstitial pulmonary infiltrates; less commonly, lobar consolidation is seen (Fig. 28.3).[59]

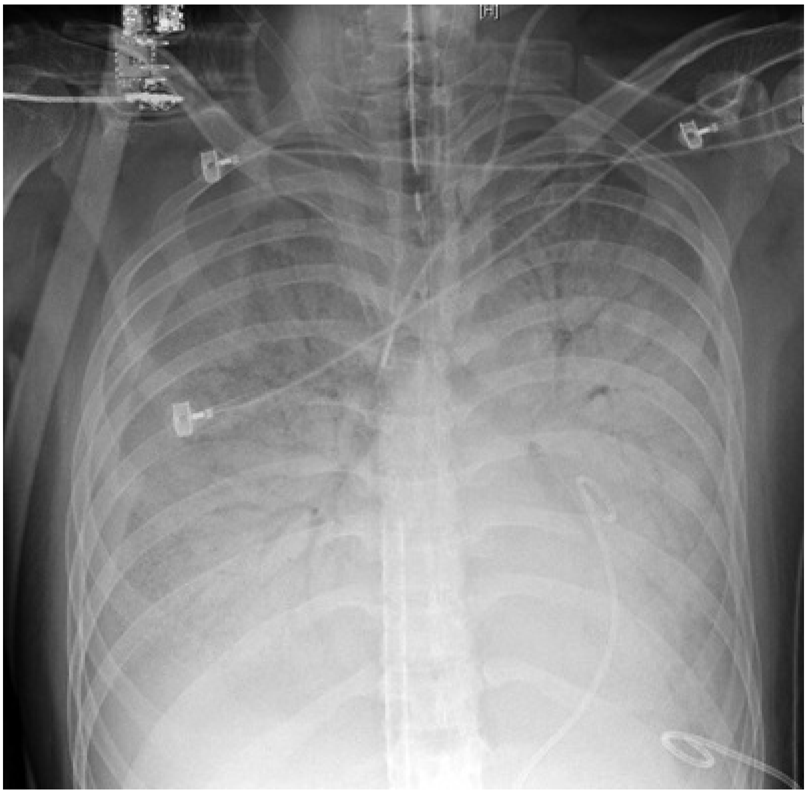

**FIG. 28.3** Chest x-ray of an adolescent boy admitted for severe adenoviral pneumonitis with acute respiratory distress syndrome requiring support with extracorporeal membrane oxygenation. The figure demonstrates extensive bilateral pulmonary infiltrates consistent with severe pneumonitis.

## Diagnosis and Differential Diagnosis

Pharyngoconjunctival fever in adenoviral infections can mimic other viral infections and is a common differential of the inflammatory condition Kawasaki disease due to conjunctival involvement as well as significant cervical lymphadenopathy. Gastroenteritis caused by adenoviral infections is similar to that caused by other viruses, such as astrovirus or norovirus. In immunocompromised patients, cytomegalovirus and Epstein-Barr virus are differentials for adenoviral enterocolitis.

Detection of the virus can be performed via antigen detection, PCR, virus isolation, or serology. Antigen testing by direct fluorescent assay of respiratory secretions (nasopharyngeal) has been shown to have a sensitivity of about 62.5% and a specificity of up to 100%.[52] PCR testing for adenovirus can be done on throat swabs, sputum, and rectal swabs with a reported sensitivity of 91%, 88%, and 86%, respectively. However, pleural effusion fluid has low pickup rates of adenovirus, estimated to be only 39%.[53] Adenoviral PCR on blood and stool samples is most useful for immunocompromised patients in cases with severe manifestations.

Blood serologic testing demonstrating a fourfold rise in the antibody titers between the acute and convalescent phases is the gold-standard diagnosis but is less commonly done owing to the development of more rapid diagnostic methods. Serotyping is not routinely performed and is used mainly for epidemiologic surveillance purposes.

## Management and Treatment

No specific treatment exists for adenoviral infections in immunocompetent individuals, and most infections are self-limited. In immunocompromised hosts, the antiviral agent cidofovir has been used to treat severe infections, and several novel therapies have been explored.[60]

The treatment of postadenoviral bronchiolitis obliterans remains largely supportive, with oxygen supplementation and bronchodilators. Corticosteroids would be an ideal theoretical treatment, since bronchiolitis obliterans is largely an immune-mediated inflammatory response, but there have been mixed results. In a study of 31 children, the use of systemic steroids in adenoviral pneumonia did not alter the progression to bronchiolitis obliterans.[61] Case series showing possible clinical benefit with intravenous methylprednisolone to treat bronchiolitis obliterans have been limited by small sample sizes and other confounders such as bronchodilator therapy. There have been no large clinical trials of the effectiveness of inhaled corticosteroids in the treatment of bronchiolitis obliterans.[62] There is evidence suggesting that latent adenoviral infection causes eosinophilic airway inflammation, leading to the ineffectiveness of steroid treatment.[63]

## Prevention

Military recruits in the United States from 1971 to 1999 were routinely vaccinated against adenovirus due to the occurrence of outbreaks. After the cessation of vaccination, more cases became apparent. A new oral live attenuated adenoviral vaccine against types 4 and 7 was approved in 2011 for use in military personnel. However, no vaccine has been used in the general public.[56]

## Prognosis

Most immunocompetent individuals recover from the infection with no sequelae. However, severe cases of adenoviral pneumonia have been reported to result in bronchiectasis or bronchiolitis obliterans, and there have been deaths from severe adenoviral lung disease, mostly in patients with major underlying illnesses. Immunocompromised hematology and transplant patients have had fatal outcomes from disseminated adenoviral infections with liver failure, respiratory disease, and disseminated infection. Fatal cases have been associated particularly with serotype 7, but other serotypes have also been reported to be associated with fatalities.[53]

# Tuberculosis

*Heather Young Highsmith MSc, MD, Jeffrey R. Starke MD, Anna Maria Mandalakas MD, PhD*

Despite advances in diagnostic tests, availability of inexpensive curative treatment, and the nearly universal use of the bacillus Calmette-Guérin (BCG) vaccines, tuberculosis (TB) was the leading infectious cause of mortality in the world in 2015. The World Health Organization (WHO) estimates that TB leads to 1.8 million deaths and 10.4 million new cases annually. One million of these cases and 210,000 deaths occur in children.[1] As long as contagious TB persists in adults, children will be affected. However, many aspects of the epidemiology, pathophysiology, and natural history of childhood TB are fundamentally different from the features of the disease in adults.

In all populations, TB, caused by the organism *Mycobacterium tuberculosis,* has several stages. *TB exposure* is the first stage, which occurs when an individual has been in close proximity to a person with contagious TB disease. The second stage is *TB infection,* which occurs when an individual has inhaled the causative organism but has no overt physical symptoms or findings on radiographic examination. *TB disease* exists when an individual manifests symptoms, signs, or radiographic manifestations consistent with *M. tuberculosis* pathology. Because the organism can develop resistance to the drugs used to treat it, the proliferation of resistant strains has become a growing public health threat. It is also important to differentiate between drug-susceptible *M. tuberculosis*—susceptible to all first-line medications used to treat it, and drug-resistant *M.*

*tuberculosis.* A thorough understanding of TB in all its stages and resistance patterns is essential to treating individual children and designing effective interventions to control it.

# Epidemiology

## Transmission

Transmission of *M. tuberculosis* is generally from person to person and occurs via inhalation of mucous droplets that become airborne when an individual with pulmonary or laryngeal TB coughs, sneezes, speaks, laughs, or sings. After drying, the droplet nuclei can remain suspended in the air for hours. Only small droplets (<10 μm in diameter) can reach alveoli. A video from the Centers for Disease Control and Prevention illustrates the transmission process as well as the pathogenesis of the disease, and is available at https://youtu.be/9112brXCOVc. Droplet nuclei can also be produced by aerosol treatments, sputum induction, aerosolization during bronchoscopy, and through the manipulation of lesions or processing of tissue or secretions in the hospital or laboratory. Transmission occurs rarely by direct contact with infected body fluids or fomites.

Many factors are associated with the risk for acquiring *M. tuberculosis* infection, including the extent of contact with a contagious person, the burden of organisms in the person's sputum and the frequency of a person's cough. Adults with pulmonary TB and bacilli present on acid-fast staining of sputum are more likely to transmit infection. Recent evidence from adult patients suggests that the magnitude of the inhaled dose of *M. tuberculosis* as measured by cough aerosols can predict an individual's risk of TB progression following exposure.[2] In addition, the risk for transmission correlates directly with the closeness of contact and amount of time spent with a contagious case.[3] Most transmission to children occurs in the home. Markers of close contact such as urban living and overcrowding correlate with acquisition of infection.[4] An increased risk for infection has been demonstrated in several institutional settings, including nursing homes, schools, correctional institutions, and homeless shelters. A growing problem concerns TB transmission in refugee and orphanage settings.[5–7] There is some evidence that the risk for acquiring infection increases with age from infancy to early adulthood, likely because of increasing likelihood of contact with infectious persons.[8]

It has been noted for decades that children with TB rarely infect other children or adults.[9] In the typical case of childhood pulmonary TB, tubercle bacilli in endobronchial secretions are sparse, and when young children with TB cough, they lack the tussive force of adults. Sputum production is rare in children, and collected specimens usually do not show acid-fast bacilli (AFB) upon staining, indicating a low concentration of organisms. However, specimens from young infants with extensive TB infiltrates, children and adolescents with cavitary lesions, or intubated children with TB are potentially infectious. The few documented cases of transmission from children have been in individuals with typical findings of adult-type TB, with lung cavities and sputum production, or infants with congenital TB who have a large burden of organisms in the lungs.[10–12] When transmission of *M. tuberculosis* has been documented in schools, orphanages or children's hospitals, it has almost invariably been from an adult or adolescent with undiagnosed pulmonary TB.[7,13,14] In fact, when a child is suspected clinically of having TB disease, the adults who accompany the child should undergo urgent testing for TB (usually by chest radiograph or AFB) sputum smear to be sure they do not spread infection in the facility.[14]

A few classic studies have investigated the factors that influence whether or not an infected person will develop TB disease. It is clear that the risk for disease is highest shortly after initial infection and declines thereafter. From infancy to age 10 years, age is inversely associated with the risk for developing disease. Children under the age of 2 are at high risk of progressing from infection to disease (25%–30%, and this risk is even higher for children under 1 year of age, 40%–50%). Furthermore, children less than 1 year of age are more likely to develop severe forms of disease, such as miliary or meningeal TB.[15] For unknown reasons, there is a second peak in the risk for developing disease during late adolescence and early adult life. Most young children who develop TB disease do so within the first year after infection, with most cases occurring within 6 months of transmission of the organism. There is also increasing evidence that certain strains of *M. tuberculosis* create an increased risk of progression to disease and an increased risk of severe disease.[16,17]

## Incidence and Prevalence

The WHO estimates that 2 billion people are infected with *M. tuberculosis*.[18] This reservoir of TB infection leads to approximately 10.4 million new TB cases and 1.8 million deaths annually.[1] Estimates of childhood TB disease did not exist prior to 2012. Several reasons contributed to the lack of reporting: (1) children not coming to health services, (2) the difficulties in diagnosis of TB disease in resource-poor settings, (3) the lack of age-disaggregated data for many countries and (4) underreporting of clinically diagnosed childhood cases. Once the WHO first started reporting global childhood TB estimates in 2012, the efforts were plagued by methodologic limitations.[19]

Mathematical modeling has since provided figures that are probably more accurate. Within the 22 countries that carry 80% of the world's burden of TB disease, it is estimated that 7.6 million children acquire TB infection each year, while 53 million children harbor the infection at any given time; of these, at least 650,000 develop TB each year.[20] Systematic review with modeling to adjust for underreporting has led to an estimate of 850,000, or 1 million children with incident TB disease annually.[21,22] In 2015, with increasing numbers of countries reporting age-disaggregated data and using similar methodology to the aforementioned studies, the WHO estimated that 1 million children develop incident TB disease annually, and 210,000 children die from TB.[1] Despite the improvement in methodology and reporting, the true number of cases remains unknown. The majority of childhood cases occur in resource-limited areas where diagnostic tests include only acid-fast staining of sputum, which is positive in up to 70% of adults but in less than 10% of children with pulmonary TB. As a result, when microbiologic confirmation is required, only one-third of the estimated number of childhood cases are ever reported to national TB programs.[1] In regions where improved case finding has been initiated, children may represent up to 39% of all cases, with a skew toward more serious and complicated cases.[1]

*M. tuberculosis* can develop resistance to therapeutic drugs if individuals are improperly treated, as discussed later in the chapter. Once an isolate has developed resistance to isoniazid (INH) and rifampin (RIF), it is considered a multidrug-resistant (MDR) organism, and when individuals develop disease from a MDR organism, it is referred to as MDR-TB. The WHO estimates that 3.3% of new TB cases in 2015 were MDR-TB cases.[1] India, China and the Russian Federation have the majority of cases of MDR-TB, but the areas with the highest rates of MDR-TB cases are clustered in eastern Europe and Central Asia, where more than 18% of new TB cases were estimated to be MDR.[1]

Children usually develop MDR-TB after inhaling already resistant organisms from an older individual with contagious TB who has been treated improperly (secondary resistance) instead of developing MDR-TB during his or her own treatment (primary resistance). Because it is difficult to isolate the organism, especially from children, on which to perform drug susceptibility testing (DST), it is difficult to estimate the number of children with MDR-TB. Two mathematical modeling studies have estimated that, globally, between 25,000 and 32,000 children develop MDR-TB annually.[21,22]

In high-resource settings, such as the United States, Canada, Australia, the United Kingdom, and many western European countries, TB incidence declined upon the advent of effective therapy and prevention. In such settings, foreign-born individuals and racial and ethnic minorities bear a disproportionate amount of TB infection and disease. Screening of immigrants and high-risk populations with connection to appropriate evaluation and treatment are key to TB control in these settings.

## The Epidemiology of Tuberculosis in Individuals Infected With Human Immunodeficiency Virus

The United Nations Program on Human Immunodeficiency Virus (HIV)/Acquired Immunodeficiency Syndrome (AIDS) estimates that there are 3.2 million children living with HIV. More than 91% of these children live in sub-Saharan Africa in high-burden TB settings.[23] Despite dramatic gains in the fight against HIV owing to successful prevention of mother-to-child transmission and the robust rollout of antiretroviral therapy, TB is the leading cause of death in people living with HIV. In 2014, HIV-associated TB deaths among adults accounted for 25% of all TB deaths (among HIV-uninfected and HIV-infected people and one-third of the estimated 1.2 million deaths from HIV/AIDS).[24] In high-burden settings, HIV-infected children are at increased risk of acquiring TB infection.[25] TB is a major cause of mortality in HIV-infected children, who have a high risk of progression to TB disease and death following TB infection.[26] HIV-infected infants and young children are at least 24 times more likely to develop culture-confirmed TB than are HIV-uninfected infants and young children.[27] Other populations to consider are HIV-uninfected and HIV-exposed but uninfected children living in a household with HIV-infected individuals. As adult caregivers with HIV infection are at risk for TB disease, all children living in HIV-affected households are more likely to be exposed and to consequently develop TB disease. Maritz has shown that HIV-infected and HIV-exposed children in a high-burden setting have similar rates of TB exposure, with TB disease being found in 19% of the HIV-infected children and 8% of the HIV-exposed children.[28] Although Madhi and colleagues have shown a high incidence of TB disease in HIV-exposed but uninfected children (41 cases per 1000 child-years), TB incidence was threefold greater in HIV-infected children (121 per 1000 child-years in the same high-burden setting).[29]

Immune-compromised HIV-infected children are prone to developing disease manifestations indicative of poor organism containment, such as cavitation of the Ghon focus and disseminated (miliary) disease.[30–32] This presentation is notably similar to that of very young non–HIV-infected children, suggesting that the immune system of both populations has difficulty controlling *M. tuberculosis*.[30,33,34] HIV-infected individuals are also at risk for other HIV-related lung pathology, such as lymphocytic interstitial pneumonia (LIP), which can present with similar symptoms and radiographic findings (see Chapter 66). The nonspecific clinical and radiographic presentations of TB disease in HIV-infected children make this a challenging diagnosis.

## Mycobacteriology

The genus *Mycobacterium* consists of a diverse group of obligate aerobes that grow most successfully in tissues with high oxygen content, such as the lungs. These nonmotile, nonspore-forming, pleomorphic rods range in length from 1 to 10 μm and in width from 0.2 to 0.6 μm. Their cell wall has a complex structure that includes a large variety of proteins, carbohydrates, and lipids. The mycolic acids are the most distinctive lipids. The lipid-rich cell wall makes them impermeable to many stains unless the dyes are combined with phenol. Once stained, the cells resist decolorization with acidified organic solvents, resulting in their hallmark trait of being "acid-fast." This property is demonstrated with basic fuchsin stain techniques, such as the Ziehl–Neelsen and Kinyoun methods, or the more sensitive fluorochrome method using auramine and rhodamine stains. It is not possible to distinguish one species of *Mycobacterium* from the others using only acid-fast staining.

Of the more than 60 species of *Mycobacterium* that have been described, about half are pathogenic in humans.[35] The *M. tuberculosis* complex consists of five main closely related species: *M. tuberculosis, M. bovis, M. microti, M. canetti,* and *M. africanum.* These organisms are commonly grown on solid media that contain an egg-and-potato base, such as Lowenstein–Jensen media or on synthetic media, such as Middlebrook agars 7H9 and 7H10. Visible growth on solid media can take 3–6 weeks. *M. tuberculosis* complex grows in only 7–10 days in liquid media; a broth formulation of Middlebrook agars is most commonly used.[36]

DST for *M. tuberculosis* can be performed on either solid or liquid media that contain standard concentrations of antimicrobial agents; the growth is compared to a control inoculation.[37] The results can take several weeks to return, as these tests depend on growth of the organism. Other newer methods of identification and DST are available and are discussed in more detail in the section titled "Diagnosis of Disease."

# Immunology

Humans display a wide spectrum of immunologic responses to *M. tuberculosis.* The varied immunologic response is reflected in the diverse clinical manifestations, ranging from asymptomatic infection with a positive tuberculin skin test (TST) or the interferon-γ release assay (IGRA) to hematogenous dissemination with severe or fatal disease.[38–40] Immunologically competent cells of the human host recognize *M. tuberculosis* by its antigens; an extraordinarily large number of these antigens have been described. In a few individuals, the innate immune system represented by macrophages, natural killer cells, and neutrophils control infection as part of the initial response to *M. tuberculosis.*[41] In the majority of infected persons, the acquired immune response is responsible for control of *M. tuberculosis* and the subsequent pathophysiologic events.

T cells, as antigen-recognition units, have critical regulatory and effector roles in the immune response to *M. tuberculosis.* In the traditional model, macrophages present antigens from phagocytosed bacilli to T cells. Antigen-activated T cells secrete cytokines, which in turn stimulate macrophages, making them more effective at controlling mycobacterial growth. Recent advances in studies of the human immune response to mycobacteria have expanded on this simple model.[42] First, a large variety of circulating and tissue-bound T-lymphocyte subsets ($CD4^+$, $CD8^+$ and γδT cells) have antigen receptors with high affinity for mycobacterial antigens.[39] Second, T cells also serve as cytotoxic effector cells against *M. tuberculosis*–infected macrophages. Third, macrophages sensitized to nontuberculous mycobacteria (NTM) or BCG vaccine produce a large number of cytokines in response to a repeat exposure to mycobacterial antigens. Of note, B lymphocyte–mediated humoral responses to mycobacterial antigens occur in patients, but they have no clearly demonstrated role in the pathogenesis of disease.

The course of infection is influenced largely by the host immune response to *M. tuberculosis.*[38–40] Most children infected with *M. tuberculosis* develop infection characterized by a positive TST or IGRA but no symptoms or radiographic abnormalities.[39] These children have an effective macrophage- and lymphocyte-activated response with a rapid expansion of T cells and production of protective cytokines and mediators. In children who develop disease, the most common manifestation is pulmonary disease, including a Ghon focus, enlarged lymph nodes or bronchial disease. However, the immune system in these children often contains the disease, which may resolve without chemotherapy.[15] A few children experience severe forms of disease, including progressive pulmonary TB, miliary or disseminated TB or TB meningitis. These forms of disease result from an immune response that fails to contain the growth of the bacilli. The risk for disease development in childhood following initial infection is inversely related to age, suggesting an inadequate or immature immune response in young children.[15,43]

Although children classically have been thought to progress from exposure to TB infection to TB disease in a linear, unidirectional fashion, a growing body of evidence suggests that a more complex, dynamic bidirectional continuum of responses exists, leading to a spectrum of TB infection and disease states (Fig. 29.1).[44] Several lines of evidence suggest that the specific acquired host defenses against mycobacteria are genetically determined. Twin studies indicate that there is a higher concordance of TB among monozygotic compared with dizygotic twins,[45,46] and segregation analysis of TB in families indicates an oligogenic pattern of inheritance.[47]

# Pathophysiology

After inhaling *M. tuberculosis*, most children do not develop disease but rather develop TB infection. These children have a positive TST or IGRA result and no clinical or radiographic evidence of TB disease. It is presumed that these children are infected with a low number of viable tubercle bacilli that do not immediately cause clinical disease. Once the organisms are inhaled, they are ingested by alveolar macrophages, which form caseating granulomas to contain the bacilli. Macrophages transport some bacilli to the regional lymph nodes. Before an adequate immune response is mounted, the bacilli can transit from the regional lymph nodes via the lymphatic duct or directly into the systemic circulation. This occult lymphohematogenous spread disseminates bacilli to various organs, where they may survive for decades.[48] Disseminated TB disease results if the dissemination is not controlled by the developing acquired immune response. The occult dissemination also provides the seed organisms for extrapulmonary TB, which accounts for 20%–30% of childhood TB cases.

In some children, tubercle bacilli reach a terminal airway and induce a localized pneumonic parenchymal inflammatory process referred to as the primary (Ghon) focus. Approximately 70% of the primary foci are subpleural. All lobes are equally affected, and 25% of children have multiple parenchymal foci. Bacilli originating from this focus drain via local lymphatics to the regional lymph nodes. The triad of the primary focus, local tuberculous lymphangitis, and enlarged regional lymph nodes is referred to as the primary complex.

## Evolution of Clinical Disease in Children

A review of information available from the prechemotherapy era provides a rich understanding of the natural evolution of clinical disease in children.[15,49] Following infection, all children progress through an asymptomatic incubation period generally lasting 3–8 weeks. The subsequent development of clinical disease is determined by the interaction of the host and the organism and is highly age-dependent (Table 29.1).[49]

**Table 29.1**

**Average Age-Specific Risk for Disease Development Following Primary Infection**

| Age at Primary Infection | Immune-Competent Children (Dominant Disease Entity Indicated in Parentheses) | Risk of Disease Following Primary Infection |
|---|---|---|
| <1 year | No disease | 50% |
| | Pulmonary disease (Ghon focus, lymph node or bronchial) | 30%–40% |
| | TBM or disseminated disease | 10%–20% |
| 1–2 years | No disease | 70%–80% |
| | Pulmonary disease (Ghon focus, lymph node or bronchial) | 10%–20% |
| | TBM or disseminated disease | 2%–5% |
| 2–5 years | No disease | 95% |
| | Pulmonary disease (lymph node or bronchial) | 5% |
| | TBM or disseminated disease | 0.5% |
| 5–10 years | No disease | 98% |
| | Pulmonary disease (lymph node, bronchial effusion or adult type) | 2% |
| | TBM or disseminated disease | <0.5% |
| >10 years | No disease | 80%–90% |
| | Pulmonary disease (effusion or adult type) | 10%–20% |

| | | |
|---|---|---|
| | TBM or disseminated disease | <0.5% |

*TBM*, Tuberculous meningitis.

The various manifestations of TB tend to occur according to a predictable timetable.[48] Disseminated TB and TB meningitis tend to be early manifestations, often presenting 2–6 months after initial infection has occurred. The primary complex and its complications become apparent most often 3–6 months after infection. It is common for untreated primary complex TB to result in calcification of the lung parenchyma and/or regional lymph nodes, a process that occurs at least 6 months after infection (Fig. 29.2). Although pleural and lymph node TB often develop within 3–9 months after infection, other extrapulmonary forms of TB, especially skeletal and renal disease, may not develop for several years.

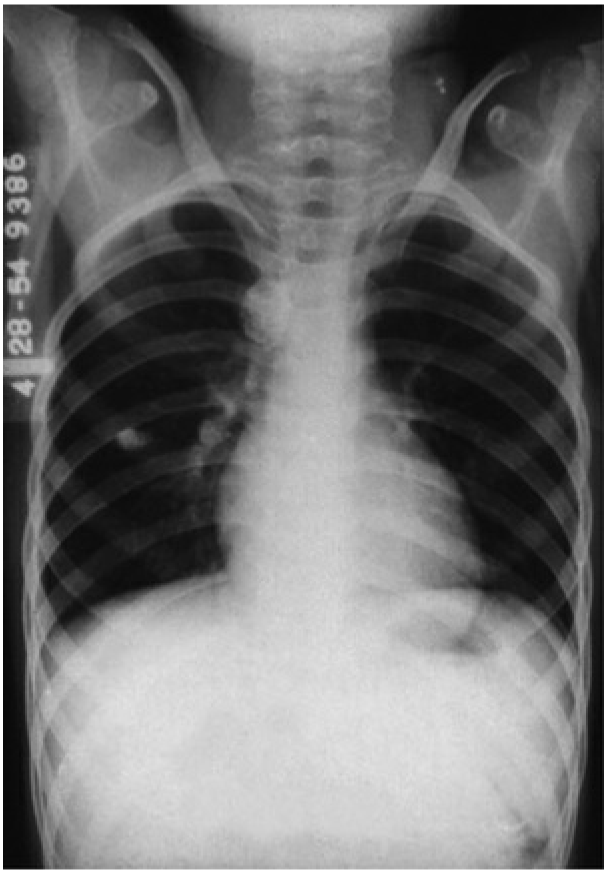

**FIG. 29.2** A calcified parenchymal lesion and lymph node in a child with tuberculosis infection. These lesions contain a small number of viable *Mycobacterium tuberculosis* organisms.

Children younger than 2 years of age are at greatest risk for both the development of disease and severe manifestations of disease. Children between 2 and 5 years of age have the next highest risk. Children between 5 and 10 years of age are at the lowest risk of progressing from infection to disease; this time span is often called the "favored age." The risk increases again in adolescence, when children are more likely to manifest adult-type disease, including cavitary disease.

# Clinical Features

## Intrathoracic Tuberculosis

Following inhalation of *M. tuberculosis* and the formation of the primary complex (see Fig. 29.2), a child can develop intrathoracic TB, which is the most common manifestation of TB disease. Intrathoracic TB consists of a spectrum ranging from subclinical to severe manifestations, which are described in the following sections.

## Isolated Lymphadenopathy

The hallmark of childhood pulmonary TB is enlargement of the regional hilar, mediastinal, or subcarinal lymph nodes on chest x-ray (Fig. 29.3).[50,51] When thoracic adenopathy is isolated without other findings, it usually causes few or no clinical signs or symptoms. This manifestation is most common soon after exposure, usually as part of active case finding.

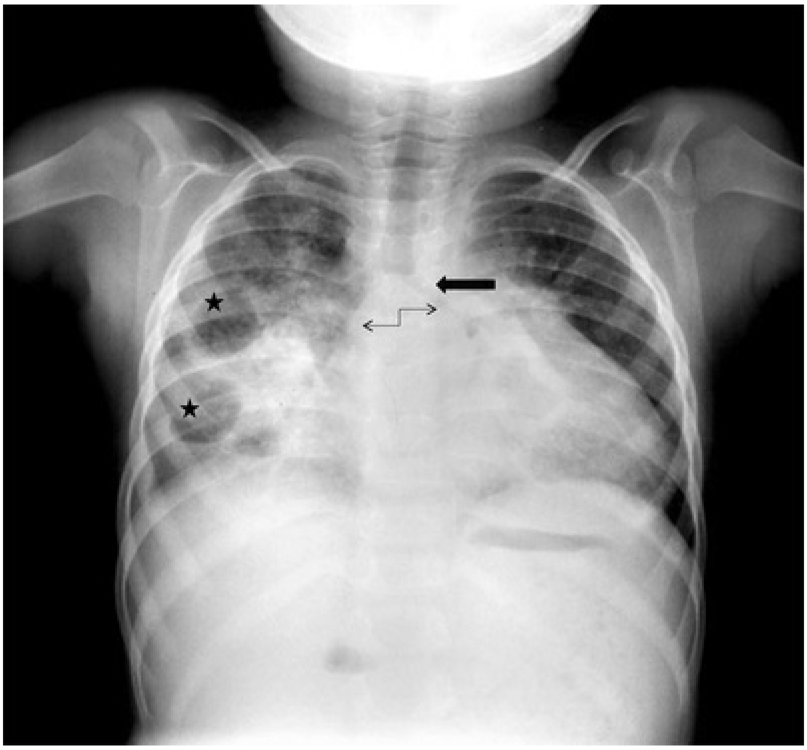

**FIG. 29.3** A young child with pulmonary tuberculosis who has developed cavitation of the lung parenchyma *(asterisk).* The *solid arrow* shows narrowing of left mainstem bronchus, while *dotted arrows* show splaying of the main bronchi.

## Progressive Primary Infection

A primary focus, without or occasionally with cavitation, may be seen in symptomatic children who have weight loss, fatigue, fever, and chronic cough.[52] If the host is unable to contain the tubercle bacilli, progressive caseation occurs in the lung parenchyma surrounding the primary focus. The area of caseation may discharge into a bronchus, resulting in the formation of a primary cavity with possible endobronchial spread (Fig. 29.4; see also Fig. 29.3). The tubercle bacilli disseminate further to other parts of the lobe and can involve an entire lung. On rare occasions an enlarging primary focus ruptures into the pleural cavity, creating a pneumothorax, bronchopleural fistula, or caseous pyopneumothorax. Profound fever, cough, and weight loss accompany a severe progressive lesion. Before the advent of chemotherapy, 25%–65% of children with progressive primary disease died. However, with appropriate therapy, the prognosis is excellent.

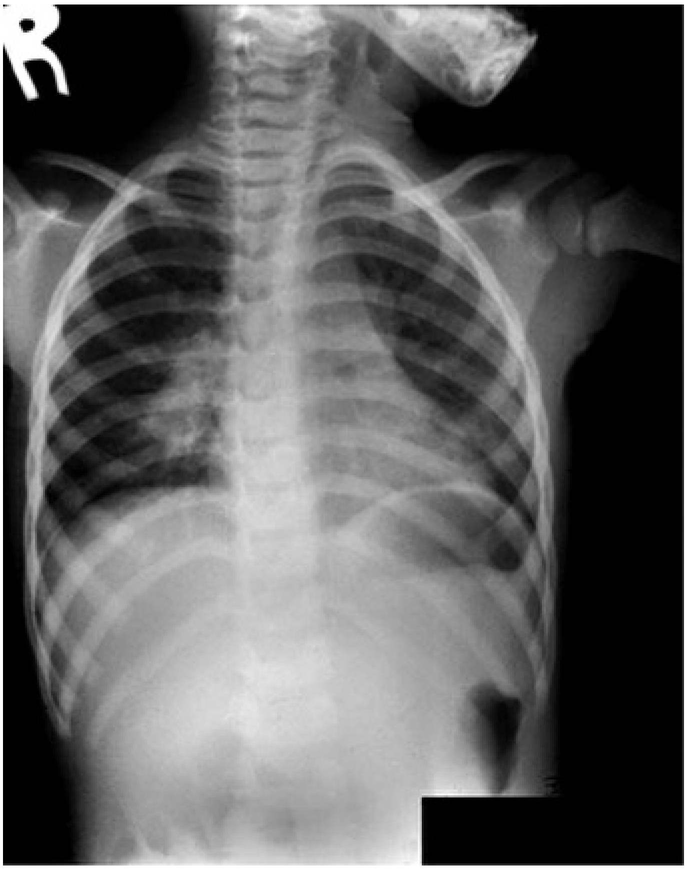

**FIG. 29.4** Hilar adenopathy in a child with early pulmonary tuberculosis. Most children with this radiographic appearance have few or no symptoms.

## Bronchial Disease

In some children, particularly infants who have smaller-caliber airways, infected lymph nodes continue to enlarge, resulting in lymphobronchial involvement, where the affected bronchus may become partially or totally obstructed because of nodal compression, inflammatory edema, polyps, granulomatous tissue, or caseous material extruded from ulcerated lymph nodes (Fig. 29.5). Although chest radiography rarely delineates the specific pathologic process causing the abnormalities, it is often apparent if bronchoscopy or a computed tomography (CT) scan of the chest is performed. The most frequently affected lobes are the right upper, right middle, and left upper lobe. Symptoms vary according to the degree of airway irritation and obstruction but frequently include localized wheezing or persistent coughing, which may mimic pertussis. A common radiographic sequence is adenopathy followed by localized hyperinflation and then atelectasis of contiguous parenchyma, referred to as collapse-consolidation or segmental lesions (Fig. 29.6A, B). However, collapse-consolidation lesions rarely produce symptoms unless the area affected is quite substantial.[53] The radiographic and clinical picture mimics foreign-body inhalation and other obstructive disorders.

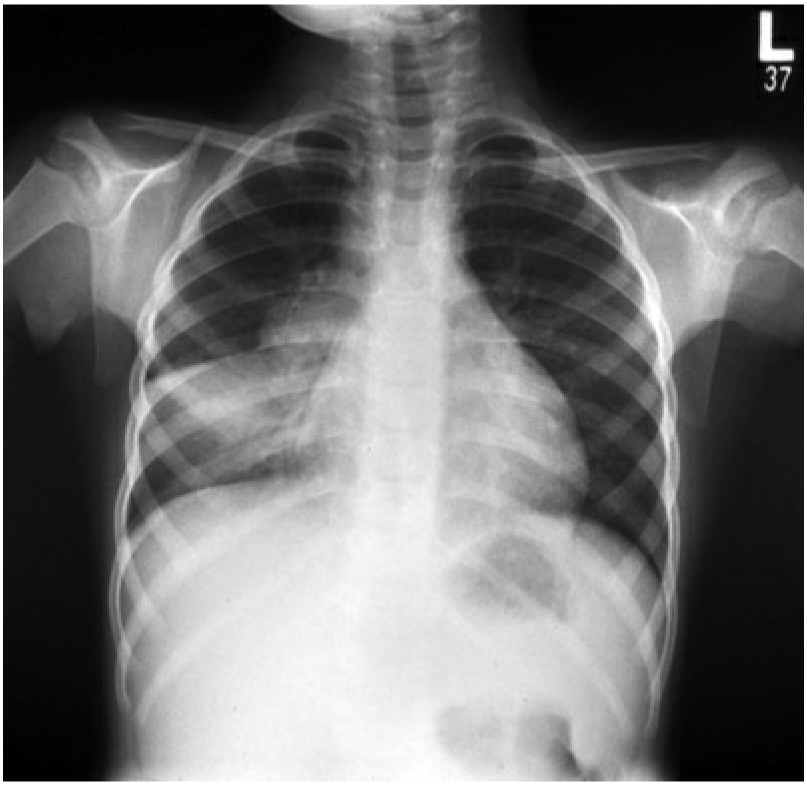

**FIG. 29.5** A classic collapse-consolidation lesion with hilar adenopathy in a child with pulmonary tuberculosis.

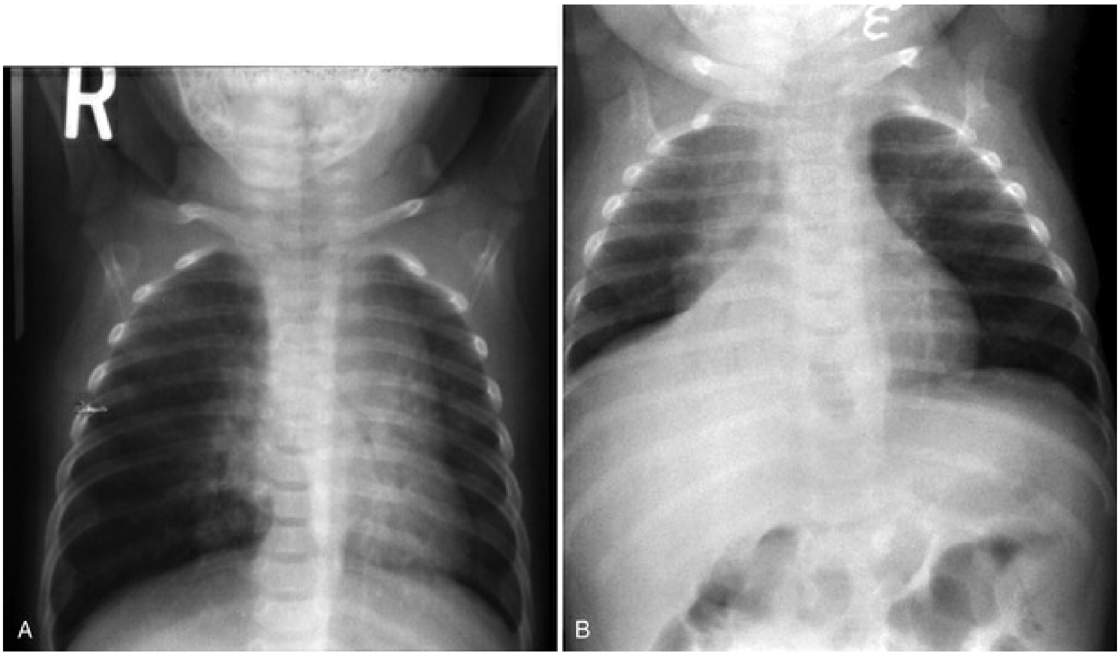

**FIG. 29.6** (A) Hyperinflation of the right lower lobe in an infant with pulmonary tuberculosis and airway obstruction. At this point the child had respiratory distress. (B) A chest radiograph from the same child several hours later shows complete collapse of the right lower lobe. At this point the respiratory distress had ceased.

Additional pathology that may accompany bronchial disease includes airway allergic consolidation, caseating consolidation, and bronchopneumonia. Children with allergic consolidation typically experience high fevers, acute respiratory symptoms, and signs of consolidation on chest radiography. Children with caseating consolidation are very ill, with high undulating fevers, chronic cough, and occasional hemoptysis (Fig. 29.7). These children are likely to have positive cultures. The affected airway is completely obstructed, and surgical intervention may be necessary to provide symptomatic relief. In some children, an acute secondary bacterial infection that occurs distal to the obstructed bronchus plays a role in the clinical picture. Children with secondary bacterial pneumonia often present with high fever, cough, and crackles. The clinical signs and symptoms often respond to antibiotics, but the chest radiographic findings do not clear because of the underlying TB.

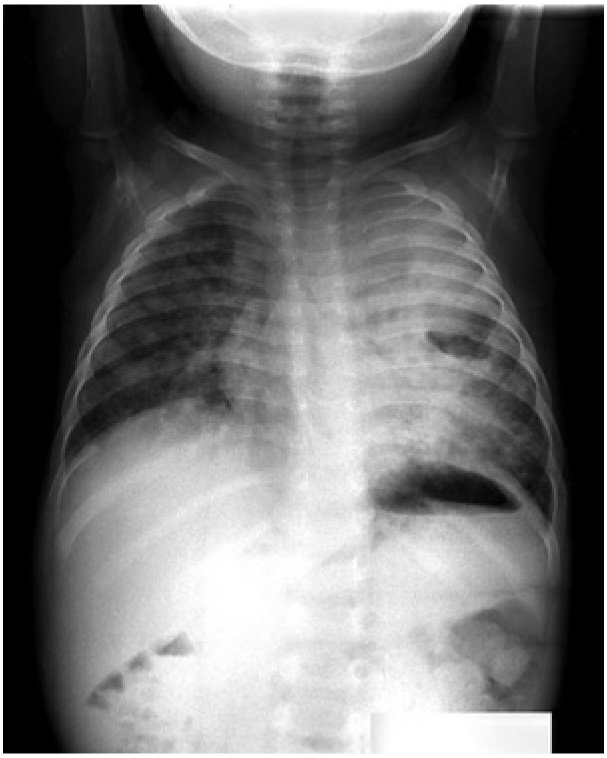

**FIG. 29.7** Pronounced caseating consolidation in a young child with pulmonary tuberculosis.

## Complicated Lymph Node Disease

Although segmental lesions and hyperaeration are the most common findings produced by enlarging thoracic lymph nodes, other problems may occur. Enlarged paratracheal nodes may cause stridor and respiratory distress. Subcarinal nodes may impinge on the esophagus and cause difficulty in swallowing, followed occasionally by the formation of an esophageal diverticulum, or the nodes may rupture directly into the esophagus and produce a bronchoesophageal fistula. Enlarged lymph nodes may compress the subclavian vein and produce edema of the hand and arm, or they may erode major blood vessels, including the aorta. They also may rupture into the mediastinum and point in the left, or more often the right, supraclavicular fossa. Compression of the left recurrent laryngeal nerve has been reported. Rupture into the pericardial sac causes tuberculous pericarditis. The late results of bronchial obstruction include the following possibilities: (1) complete reexpansion of the lung and resolution of the radiographic findings; (2) disappearance of the segmental lesion, with residual calcification of the primary focus or the regional lymph nodes; or (3) scarring and progressive contraction of the lobe or segment usually associated with bronchiectasis (Fig. 29.8). Permanent anatomic sequelae result from segmental lesions in approximately 60% of all cases, even though the abnormality is usually not apparent on plain radiographs. Cylindric (rarely saccular) bronchiectasis, stenoses, and elongation or shortening can be demonstrated on bronchography. Fortunately most of these abnormalities are asymptomatic in the upper lobes. However, secondary infection may occur in the middle and lower lobes and cause the middle-lobe syndrome.

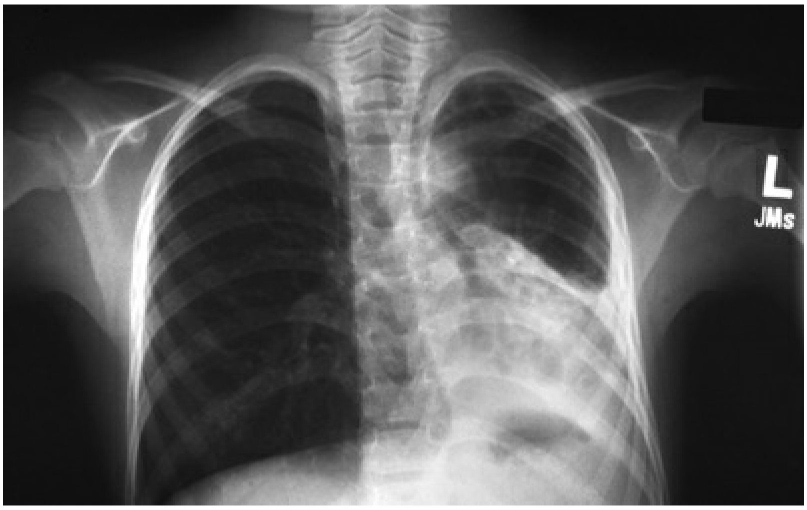

**FIG. 29.8** Bronchiectasis of the left lower lobe in a child with tuberculosis who was nonadherent to appropriate treatment.

In adults, symptomatic endobronchial TB has been treated with various interventional bronchoscopic techniques including endobronchial stenting, balloon dilation, and argon plasma coagulation.[54] There are no data supporting these interventions in children. When children are symptomatic from endobronchial disease, corticosteroids are a useful adjunct to antitubercular therapy in order to decrease the amount of airway inflammation.

## Acute Pneumonia

TB can also produce an acute infection that is clinically and radiographically indistinguishable from acute pneumonia. A systematic review assessing the contribution of TB to pneumonia in children in high-burden areas found many studies reporting that children with TB had a cough duration of less than 1 week. This is in contrast to many case management guidelines calling for evaluation for TB in the presence of a chronic cough. Inpatient case-fatality rates for pneumonia associated with TB ranged from 4% to 21% in the four clinical studies that reported pathogen-related outcomes.[55] A seminal study from Zambia found that among hospitalized children who died of acute respiratory disease, 20% had TB on necropsy.[56] Many children in this study were also found to have simultaneous pyogenic pneumonia with TB (12 of 80 patients with dual diagnoses). In another study in Uganda, 18.9% of children presenting with acute pneumonia had pulmonary TB, which was associated with being less than 5 years of age and having a TB contact.[57] Providers in high-burden settings should be aware that TB can present as an acute pneumonia or with simultaneous pyogenic infection, especially in younger children and those with a history of a TB contact.

## Adult-Type Disease

Chronic pulmonary TB, often called the adult type, or reactivation TB, occurs when pulmonary tissue has been previously sensitized to *M. tuberculosis* at primary infection and an isolated focus of organisms begins proliferating in that tissue. Chronic pulmonary TB rarely develops in children who acquired infection with *M. tuberculosis* before 10 years of age and is especially rare among children less than 2 years of age. It occurs more common when TB infection is acquired close to the onset of puberty. The preponderance of evidence supports the concept that most cases of reactivation TB result from endogenous reinfection with the dormant bacilli. However, reinfection with a different strain of *M. tuberculosis* leading to typical adult-type TB has been documented.

Reactivation pulmonary TB arises from the small round foci of organisms in the apices of the lungs (often called Assmann or Simon foci) resulting from the lymphohematogenous spread at the time of the initial infection.[58] Fibronodular infiltrates in one or both upper lobe apices are most common, but more extensive pulmonary involvement leads to diffuse consolidation or cavitation (Fig. 29.9).

Involvement of thoracic lymph nodes is usually absent. Cough, remitting fevers, night sweats, chest pain, sputum production, and hemoptysis are the most common clinical manifestations.

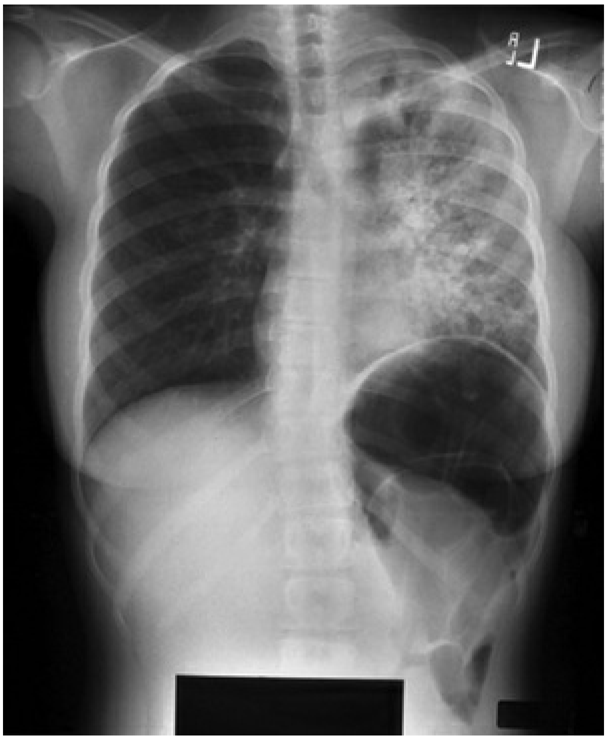

**FIG. 29.9** A chest radiograph of an adolescent girl with chronic pulmonary tuberculosis.

## Pleural Disease

Pleural TB results from the direct spread of caseous material from a subpleural parenchymal or lymph node focus or from hematogenous spread.[58–60] Pleural TB is uncommon in children younger than 6 years of age and rare in those younger than 2 years of age. The presence of caseous material in the pleural space may trigger a hypersensitivity reaction, with the accumulation of serous straw-colored fluid containing few tubercle bacilli. This exudate has a high protein concentration and lymphocyte predominance; the number of polymorphonuclear cells depends on the acuteness of onset. Although direct microscopy is usually negative, culture yields may be as high as 40%–70%. However, molecular tests such as GeneXpert are not recommended for pleural fluid owing to their low sensitivity.[61] Pleural biopsy often demonstrates caseating granulomas and increases the culture yield if ample tissue is collected. The clinical course associated with pleural involvement characteristically begins with acute chest pain, accompanied by high fever in the absence of acute illness, an ill-defined loss of vigor, and a dry cough. Active caseation in the pleural space may cause thick loculated pus containing many tubercle bacilli (Fig. 29.10). The prognosis for children with tuberculous pleural effusion has always been good compared with other overt forms of TB, even before chemotherapy was available.

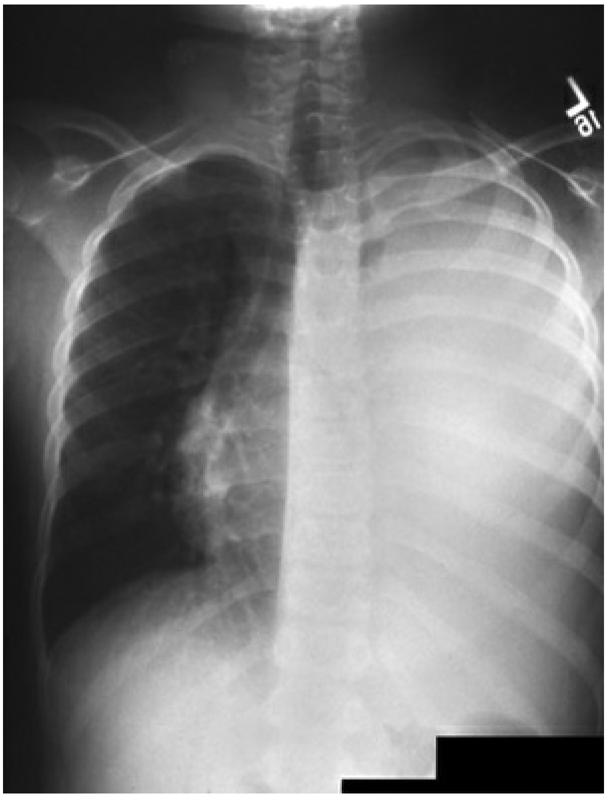

**FIG. 29.10** A large tuberculous pleural effusion in an 11-year-old girl.

## Extrapulmonary Disease

Tubercle bacilli from the lymphadenitis of the primary complex are disseminated during the incubation period in all cases of TB infection. The clinical picture produced by lymphohematogenous spread is probably determined by host susceptibility at the time of spread and by the quantity of tubercle bacilli released. Three clinical forms of dissemination are recognized:

1. The lymphohematogenous spread may be occult, in which case it usually remains so, or it may be occult initially with metastatic extrapulmonary lesions appearing months or years later (e.g., renal TB).
2. So-called protracted hematogenous TB, rarely seen today, is characterized by high spiking fever, marked leukocytosis, hepatosplenomegaly, and general glandular enlargement, sometimes with repeated evidence of metastatic seeding in the choroid plexus, kidney, and skin. Calcifications may appear subsequently, often in large numbers, in the pulmonary apices (Simon foci) and in the spleen, thus attesting to the earlier dissemination of tubercle bacilli via blood. The TST is usually strongly positive. Bone marrow biopsy may confirm the clinical impression, but treatment must often be started on a presumptive basis. Although this type of TB often ended tragically in TB meningitis in past years, today it is completely treatable if diagnosed in time.
3. The third form of lymphohematogenous spread, analogous to sepsis with pyogenic bacteria, is miliary TB. It usually arises from discharge of a caseous focus, often a lymph node, into a blood vessel such as a pulmonary vein. It may be self-propagating, with repeated discharge arising at various sites. Most common during the first 2–6 months after infection in infancy, it can arise even in adults who have apparently well-healed calcified lesions.

The clinical picture of miliary TB varies greatly, probably depending on the number of bacilli in the bloodstream.[34,62] Sometimes the patient is afebrile and appears to be well, and the condition is diagnosed by chance during contact investigation of another individual with infectious TB. The onset can be insidious, often occurring after the patient has had another precipitating infection. In rare cases, the onset is abrupt. Drowsiness, loss of weight and appetite, persistent fever, weakness, rapid breathing with a rustling sound on auscultation of the lungs, occasionally cyanosis and almost always a palpable spleen are the clinical manifestations that lead the clinician to obtain a chest radiograph.

Usually, within no more than 3 weeks after the onset of symptoms, tubercles, sometimes tiny and at times large, can be seen evenly distributed throughout both lung fields (Fig. 29.11). In the initial stages, they are often detected best on a lateral view of the retrocardiac space. Recurrent pneumothorax, subcutaneous emphysema, pneumomediastinum, and pleural effusion are less serious but well-recognized complications of miliary TB. Cutaneous lesions—including painful nodules, papulonecrotic tuberculids and purpuric lesions—may appear in crops. In addition, choroid tubercules can be noted on ophthalmologic exam and are specific for the diagnosis of miliary TB. The diagnosis of disseminated TB is usually established by means of the clinical picture and a chest radiograph; sometimes by a liver or skin biopsy; by culturing *M. tuberculosis* from the gastric aspirate, sputum, urine, or bone marrow; or by fiberoptic bronchoscopy. Treatment is usually very successful.

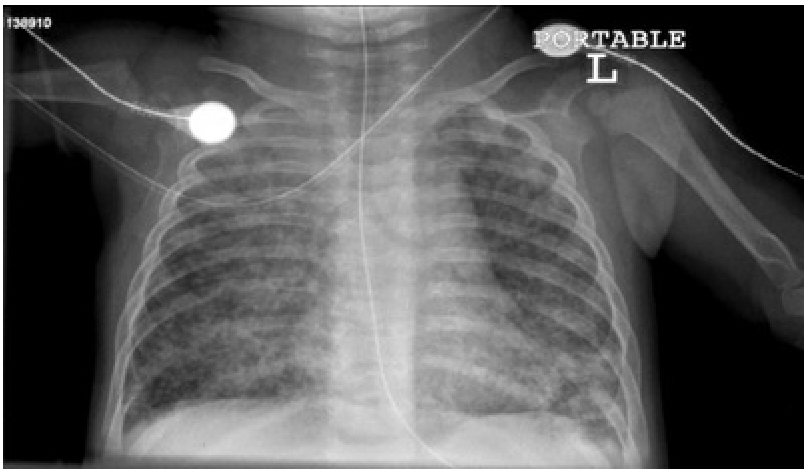

**FIG. 29.11** The appearance of miliary tuberculosis in the chest radiograph of an infant.

## Extrathoracic Tuberculosis

A complete description of extrathoracic TB is beyond the scope of this chapter. However, pulmonologists may encounter this possibility in evaluating children with pulmonary involvement and other manifestations. The most common forms of extrathoracic disease in children include TB of the superficial lymph nodes (scrofula) and the central nervous system. Other rare forms of extrathoracic disease in children are osteoarticular, abdominal, gastrointestinal, genitourinary, cutaneous, and congenital disease.

TB of the superficial lymph nodes (scrofula) is the most common form of extrathoracic disease.[63,64] Although this disease is also associated with *M. bovis* acquired by drinking unpasteurized cow's milk or cheese, most current cases occur after primary pulmonary infection with *M. tuberculosis* within 6–9 months of initial infection. Children between the ages of 5 and 10 years, followed by children over the age of 10 years, are most likely to have this presentation, but scrofula can occur in any age group. Scrofula occurs when primary lesions of the upper lung fields or abdomen extend to involve the supraclavicular, anterior cervical, tonsillar and submandibular nodes. In children, TB of the skin or skeletal system rarely leads to involvement of the inguinal, epitrochlear, or axillary lymph nodes. Early during infection, lymph nodes are discrete, firm, and nontender. The lymph nodes become fixed to surrounding tissues and feel matted as the infection progresses. Low-grade fever may be the only systemic symptom. Although usually present, a primary pulmonary complex is visible radiologically only 30%–70% of the time. TST or IGRA results are usually reactive. Although spontaneous resolution is possible, untreated lymphadenitis frequently progresses to caseating necrosis, capsular rupture and spread to adjacent nodes and overlying skin. Rupture through the skin results in a draining sinus tract that may require surgical removal. Excisional biopsy and culture of lymph nodes are often required to differentiate between TB and NTM disease.

Central nervous system disease is the most serious complication of TB in children and complicates approximately 0.5% of untreated primary infections. It is most common in children 6 months to 4 years of age and generally occurs within 2–6 months of primary infection.[65] Central nervous system disease arises from the formation of a caseous lesion in the cerebral cortex or meninges that results from early occult lymphohematogenous spread.[66] Lesions enlarge and discharge bacilli into the subarachnoid space, leading to an exudate that infiltrates the cortical and meningeal blood vessels. This results in inflammation, obstruction, and subsequent infarction of the cerebral cortex. The clinical onset of TB meningitis can be rapid or gradual. Infants and children are more likely to experience a rapid progression to hydrocephalus, seizure, and cerebral edema over several days (Fig. 29.12). In most children, signs and symptoms progress over several weeks, beginning nonspecifically with fever, headache, irritability, and drowsiness. Disease often advances abruptly with symptoms of lethargy, vomiting, nuchal rigidity, seizures, hypertonia, and focal neurologic signs. The final stage of disease is marked by coma, hypertension, decerebrate and decorticate posturing, and eventual death. Rapid confirmation of TB meningitis can be extremely difficult, with wide variability in cerebrospinal fluid characteristics and nonreactive TSTs in 40% of cases. Although some older studies reported normal chest radiographs in 50% of cases, more recent reports indicate that 80% of young children with TB meningitis have significant abnormalities on chest radiography. Since improved outcomes are associated with prompt treatment, empiric antituberculosis therapy should be instituted for any child with basilar meningitis and hydrocephalus or cranial nerve involvement that has no other apparent cause.

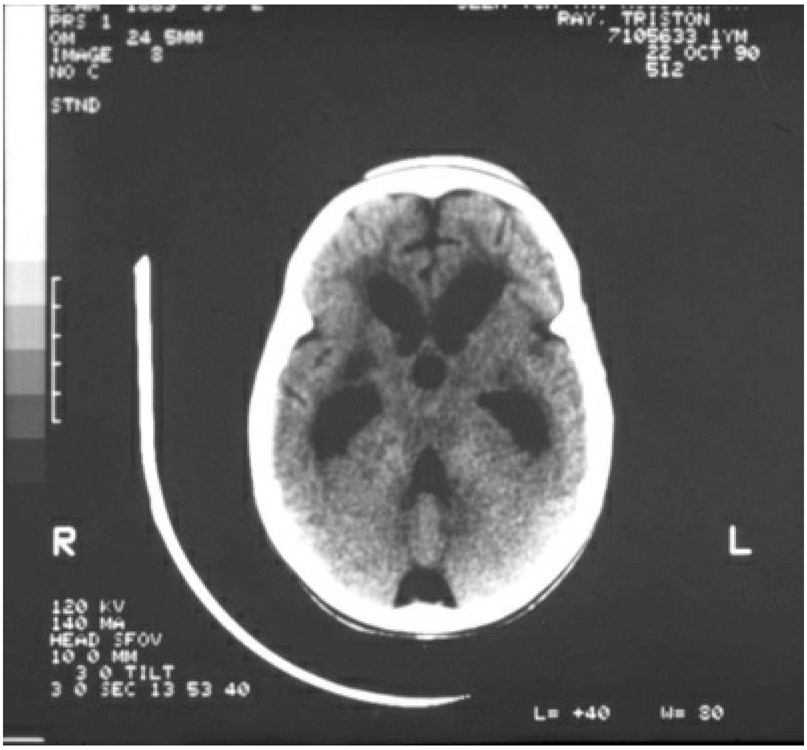

**FIG. 29.12** A computed tomography scan of the head demonstrating the communicating hydrocephalus that is typical of tuberculosis meningitis.

### Tuberculosis and Human Immunodeficiency Virus

Immune-compromised HIV-infected children have a higher risk of developing extrapulmonary disease manifestations indicative of poor organism containment, such as tuberculomas and disseminated (miliary disease).[30–32] Their presentations are notably similar to those of very young non–HIV-infected children. Lack of an age-related difference in disease presentation suggests that immune maturation is less relevant in HIV-infected children.[30] Because of the common presence of other HIV-related lung pathology on chest x-ray, such as LIP, it is often challenging to diagnose TB accurately, particularly disseminated (miliary) disease. These tremendous diagnostic difficulties result in a tendency to overdiagnose TB in this vulnerable group of children. When pulmonary TB develops in an HIV-infected child, the response to standard short-course TB therapy has lower cure rates and higher mortality, but HIV-infected children can still recover with appropriate therapy.[32,67] However, these children can develop sequelae such as bronchiectasis if TB therapy and antiretroviral therapy (ART) are delayed.[68] TB may further hasten the progression of HIV disease by increasing viral replication and depleting CD4$^+$ T lymphocytes.[69] The confirmation of TB disease in HIV-infected children is complicated by the low yield of culture and chronic HIV-related comorbidities.[31]

# Diagnosis

## Diagnostic Imaging

Various imaging modalities can be used to evaluate for intrathoracic TB. Ultrasonography is increasingly used as a point-of-care test in many settings to detect mediastinal lymphadenopathy and pleural fluid because of it has the advantages of lack of radiation, ease of interpretation, potential for portability and rapid results. However, this requires significant performer training. CT is another option that is available in some settings. It provides high definition of the lung parenchyma and mediastinal structures, which is useful if the chest x-ray findings require further delineation, such as determining if a density is due to prominent vasculature or lymphadenopathy. However, CT uses a significant amount of radiation, requires intravenous contrast and is costly. These issues limit CT use in low-resource settings.

## Chest Radiography

Chest radiography was the first diagnostic test outside of stain and culture that assisted in the diagnosis of TB. Radiography services are available in high-burden low-resource settings but are more likely to be located at referral centers than at decentralized providers. Many of the pathognomonic findings of TB can be seen on plain chest radiographs. Posteroanterior and lateral images have the most utility. Parenchymal disease, such as that found early in progressive primary infection or in acute pneumonia, appears to be identical to other airspace diseases as a nonspecific infiltrate. These areas can calcify and subsequently appear as hyperlucencies on imaging. If parenchymal disease is untreated, the area can develop a cavity, which manifests itself as a hyperlucent ring devoid of airspace markings on the interior (see Fig. 29.3).

The hallmark of pediatric TB is intrathoracic lymphadenopathy, which can manifest in a multitude of ways on radiography. Lymph nodes appear as a soft tissue density on radiography. Because these nodes commonly occur in the hilum and mediastinum, it is often difficult to differentiate these densities from the other soft tissues, such as the thymus and major blood vessels. It is often easier to see the consequence of lymphadenopathy rather than the lymph node itself. Once the lymph nodes become enlarged, they can affect nearby structures in several ways. Large lymph nodes can exert mass effect on the airways. For example, enlarged subcarinal nodes can push on the mainstem bronchi and cause the bronchi to appear splayed (see Fig. 29.3). Lymph nodes can also impinge on the airway, causing a narrowing of the airway that is notable on imaging (Fig. 29.13), with distal hyperinflation from a ball-valve effect (see Fig. 29.6A), or they may cause secondary collapse of the distal segment, manifesting as a fan-shaped consolidation (see Fig. 29.6B). When not exerting a mass effect, hilar lymph nodes can also be noted on posteroanterior images as enlargement of the mediastinal silhouette (Fig. 29.14A). On lateral images, lymphadenopathy densities can produce what is known as the "donut sign" in the posterior mediastinum, comprising the great vessels of the heart superiorly and the hilar lymphadenopathy inferiorly (Fig. 29.14B).

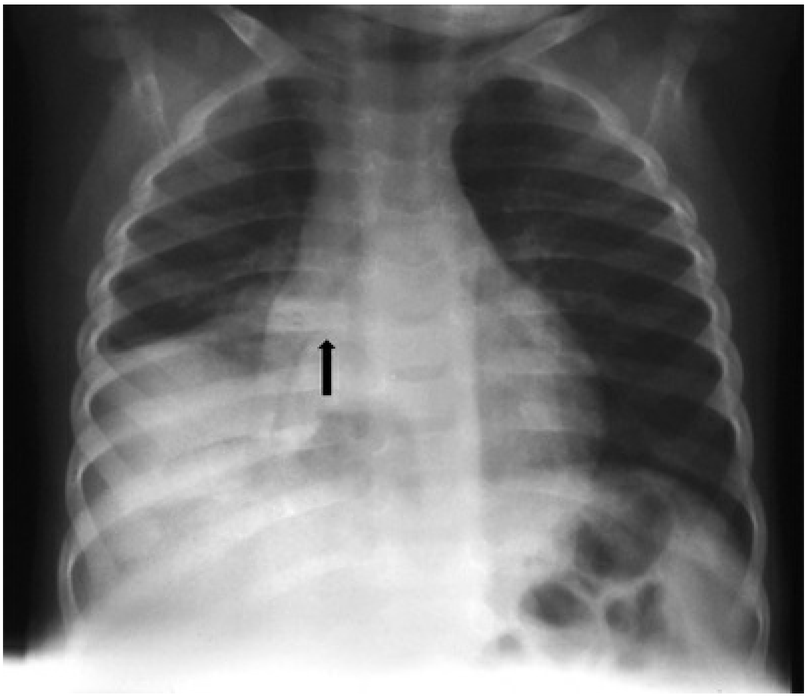

**FIG. 29.13** Posteroanterior view of a child with right-lower-lobe infiltrate and narrowing of the right mainstem bronchus *(solid arrow).*

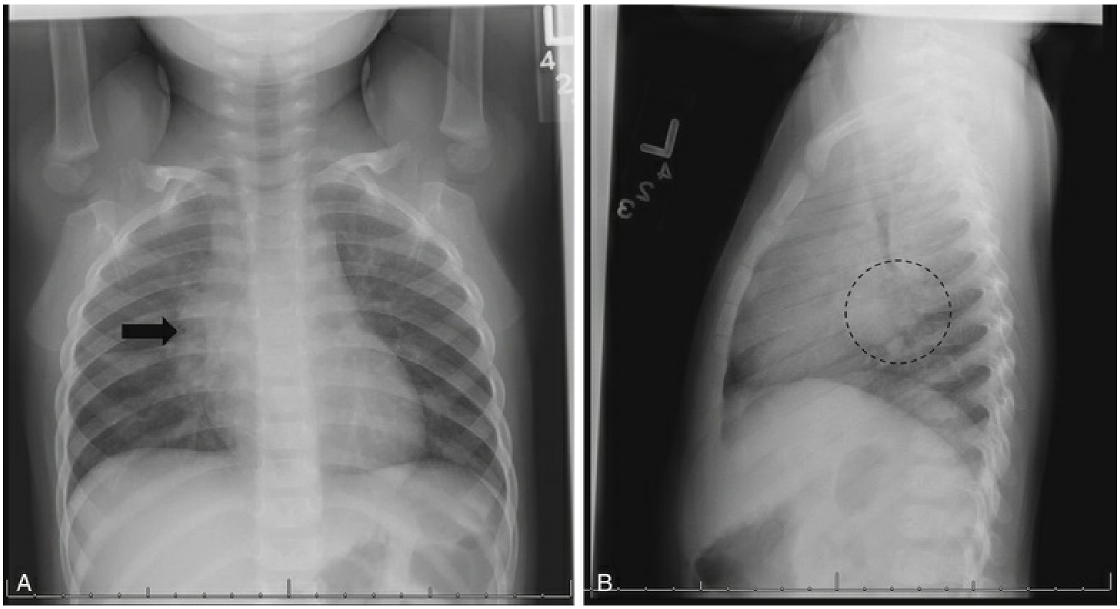

**FIG. 29.14** (A) Posteroanterior view of a child with right hilar lymphadenopathy *(solid black arrow).* (B) Lateral view of same child with a "donut sign" within the dotted circle comprising the great vessels superiorly and subcarinal lymph nodes inferiorly.

Interpretations of chest radiography findings can vary between clinicians. Du Toit compared three experienced pediatric radiologists' interobserver and intraobserver interpretations of chest radiographs and found that the radiologists agreed on the presence of lymphadenopathy with a kappa of 0.40, which indicates only moderate agreement. Agreement between a radiologist's first read of an image and a second read after weeks of delay was higher but still offered only moderate agreement (a kappa of 0.55).[70] This illustrates the difficulties in assessing intrathoracic lymphadenopathy, and consequently TB, in pediatric films. Several standardized approaches have been recommended for radiologic interpretation of childhood TB, but these are not always utilized.[49,71–73]

# Tests of Infection

## Tuberculin Skin Test

The TST remains the most widely employed test for the diagnosis of TB disease and infection in children. The sensitivity and specificity of the TST are significantly affected by several factors; these are reviewed in this section.

Infection with *M. tuberculosis* produces a delayed-type hypersensitivity reaction to specific antigenic components of the bacilli that are contained in extracts of culture filtrates called *tuberculins.* A batch of purified protein derivative (PPD), called PPD-S, produced by Siebert and Glenn in 1939, serves as the standard reference material worldwide. In response to the antigen, previously sensitized T cells release lymphokines that induce local vasodilation, edema, fibrin deposition and recruitment of other inflammatory cells.[74] The reaction begins 5–6 hours after injection and reaches maximal induration at 48–72 hours, the time when the test should be interpreted. Variability of the results of the TST may be reduced by careful attention to details of administration and reading, which should be done by trained professionals. The diameter of induration should be measured transversely to the long axis of the forearm and recorded in millimeters. Use of the ballpoint pen method developed by Sokal minimizes interobserver variability. In some individuals, the reaction may peak after 72 hours, and the largest reaction size at any time after 48 hours is considered the result. Vesiculation and necrosis occur rarely. In these cases, the result is always considered positive and repeat tuberculin testing should be avoided. A video from the Grey Bruce Health Unit in Ontario demonstrates TST administration and is available at https://www.youtube.com/watch?v=bR86G-itrTQ.

The size of the area of induration should be interpreted within the view of the child's risk of having acquired TB infection and the risk of progressing to TB disease. TST interpretation is dependent on the clinical setting. In the United States and Canada, 5 mm is used as the smallest area of induration that can be positive for the highest-risk groups, such as children with HIV infection, signs of TB disease, or recent exposure to a known TB case. An area of induration 15 mm or greater is positive even for an individual with no risk factors for disease. Guidelines for TST interpretation in the United States are available in Box 29.1. The United Kingdom now uses a universal size of 5 mm as positive.[75] The WHO recommends use of a cutoff of 10 mm for most children and a cutoff of 5 mm in immunosuppressed children.[76] WHO guidelines are followed in most countries.[77] A nonreactive TST does not exclude TB infection or disease. Several factors can diminish tuberculin reactivity resulting in a false-negative reaction (Box 29.2). The administration of live-attenuated vaccines results in immune system suppression that appears more than 48 hours after vaccination. Tuberculin skin testing may be performed on either the same day as vaccination with live virus or 4–6 weeks later. Studies have demonstrated that up to 10% of immunocompetent children with reactive anergy tests and culture-confirmed pulmonary TB have false-negative reactions to tuberculin testing.[78]

**Box 29.1**

## Definitions of a Positive Tuberculin Skin Test Result in Infants, Children, and Adolescents

### Induration ≥5 mm

- Children in close contact with known or suspected contagious case of tuberculosis disease
- Children suspected to have tuberculosis disease: Findings on chest radiograph consistent with active or previously active tuberculosis
- Clinical evidence of tuberculosis disease

Children receiving immunosuppressive therapy or with immunosuppressive conditions, including human immunodeficiency virus (HIV) infection

### Induration ≥10 mm

- Children at increased risk for disseminated disease: those younger than 4 years of age
- Those with other medical conditions, including Hodgkin disease, lymphoma, diabetes mellitus, chronic renal failure or malnutrition

Children with increased exposure to tuberculosis disease:

- Those born or whose parents were born in high-prevalence regions of the world
- Those frequently exposed to adults who are infected with HIV, homeless, users of illicit drugs, residents of nursing homes, incarcerated or institutionalized or migrant farm workers
- Those who travel to high-prevalence regions of the world

### Induration ≥≥15 mm

Children 4 years of age or older without any risk factors

**Box 29.2**

## Factors Causing False-Negative Tuberculin Skin Test Results

### Factors Related to the Person Being Tested

Infections
Viral (measles, mumps, chickenpox, human immunodeficiency virus)
Bacterial (typhoid fever, brucellosis, typhus, leprosy, pertussis, overwhelming tuberculosis, tuberculosis pleurisy)
Fungal (blastomycosis)
Live virus vaccinations (measles, mumps, polio, varicella)
Metabolic derangements (chronic renal failure)
Low protein states (severe protein depletion, afibrinogenemia)
Diseases affecting lymphoid organs (Hodgkin disease, lymphoma, chronic leukemia, sarcoidosis)
Drugs (corticosteroids and other immunosuppressive agents)
Age (newborns, elderly patients with “waned” sensitivity)
Stress (surgery, burns, mental illness, graft-versus-host reactions)

### Factors Related to the Tuberculin Used

Improper storage (exposure to light and heat)
Improper dilutions
Chemical denaturation
Contamination
Adsorption (partially controlled by adding Tween 80)

## Factors Related to the Method of Administration

Injection of too little antigen
Subcutaneous injection
Delayed administration after drawing into syringe
Injection too close to other skin tests

## Factors Related to Reading the Test and Recording Results

Inexperienced reader
Conscious or unconscious bias
Error in recording

In many of these children, TST conversion occurs after several months of treatment, suggesting that the infection was recently acquired or resulted in suppression of the immune response. Skin testing results were available in nearly all (95.4%) children reported to have newly diagnosed TB in the United States between 1993 and 2001. Of these children, 11% had negative skin test results as defined by CDC guidelines.[79] Of note, children who were diagnosed with disseminated or meningeal TB were less likely to have a positive TST result (57.6% and 54.6%, respectively) than those with pulmonary TB (90.6%).

A number of factors have been associated with false-positive tuberculin reactions and decreased tuberculin test specificity. Because some antigens in PPD are shared with other mycobacteria, false-positive reactions can occur in children who have been infected with other mycobacteria or who have been vaccinated with BCG. Exposure to NTM varies geographically and generally results in smaller, transient indurations than those caused by *M. tuberculosis*. The degree of BCG cross-reactivity is dependent on a number of factors, including strain of BCG employed, repeated BCG vaccination, age and nutritional status at vaccination, frequency of skin testing, and years since vaccination.[80–83] In most studies of children who received a BCG vaccine during the newborn period, only 50% reacted to tuberculin testing at 12 months, and 80%–90% lose reactivity within 2–3 years. Although BCG vaccination of older children or adults results in greater initial and more persistent cross-reactivity, most of these individuals lose cross-reactivity within 10 years of vaccination. Most guidelines currently suggest that the TST should be interpreted in the same way for patients who have and have not received a BCG vaccination; however, this will lead to some children with false-positive TST results being treated. A growing body of evidence now demonstrates that the impact of infant BCG vaccination on TST responses in children exposed to TB wanes with age, but in young BCG-vaccinated children, a TST cutoff of 5 mm is associated with poor specificity.[83–86] Nevertheless, as young children have the greatest risk of progression from infection to disease and are also the most susceptible to severe disseminated forms of TB disease, test sensitivity remains more important than specificity in evaluating children in this age group.

## Interferon-Gamma Release Assays

The identification of genes in the *M. tuberculosis* genome that are absent from *M. bovis* BCG[87] and most NTM[88] has supported the development of more specific tests for the detection of *M. tuberculosis*.[89] *M. bovis* BCG has 16-gene deletions, including the region of difference 1 (RD-1) that encodes for early secretory antigen target-6 (ESAT-6) and culture filtrate protein 10 (CFP-10).[88,90] ESAT-6 and CFP-10 are strong targets of the cellular immune response in patients with *M. tuberculosis* infection and disease.[91,92] In people with TB infection or disease, sensitized memory/effector T cells produce IFN-$\gamma$ in response to *M. tuberculosis* antigens, forming the biologic basis for both the TST and IGRAs. Research over the past two decades[89,93] has resulted in the development of two commercial brands of IGRAs that are approved for use in Europe and the United States. In brief, the

Quantiferon assays (QFTs; Cellestis Limited, Australia)[94] are enzyme-linked immunosorbent assay (ELISA)–based whole blood assays measuring the amount of IFN-$\gamma$ produced in response to *M. tuberculosis*–specific antigens. In contrast, the enzyme-linked immunospot (ELISPOT)–based test (T.SPOT.TB; T.Spot; Oxford Immunotec, Abingdon, Oxfordshire, United Kingdom)[95] uses peripheral mononuclear cells to detect the number of INF-$\gamma$–producing T cells. Of note, both commercial IGRAs also measure a response to a negative control and a nonspecific positive control stimulant, such as phytohemagglutinin (PHA). Results are then interpreted on the basis of a comparison of the magnitude of the response to the *M. tuberculosis*–specific stimulus compared with the negative controls. A lack of response to the positive control is interpreted as an indeterminate (Quantiferon) or invalid (T-SPOT.TB) result. Similarly, a robust response to the negative stimuli is considered an invalid or indeterminate result.

In the absence of a gold standard for infection, studies have assessed the performance of IGRAs in children with bacteriologically confirmed and clinically diagnosed TB disease. A systematic review of these pediatric studies estimated the specificity of commercially approved IGRAs for detecting *M. tuberculosis* infection at 91% for the ELISA-based tests and 94% for the ELISPOT-based test, compared with 88% for the TST (positive defined as 10 mm).[96] Estimates of test sensitivity were similar for the three tests: 83% (QFT assays), 84% (T.SPOT) and 84% (TST), respectively. Similarly, a second pediatric systematic review found the performance of the TST and QFT assays to be no different but noted that a qualitative review of four pediatric studies suggested that the QFT assays were more specific for the detection of TB infection in children compared with the TST.[97] Like the TST, IGRAs cannot differentiate between TB infection and TB disease.

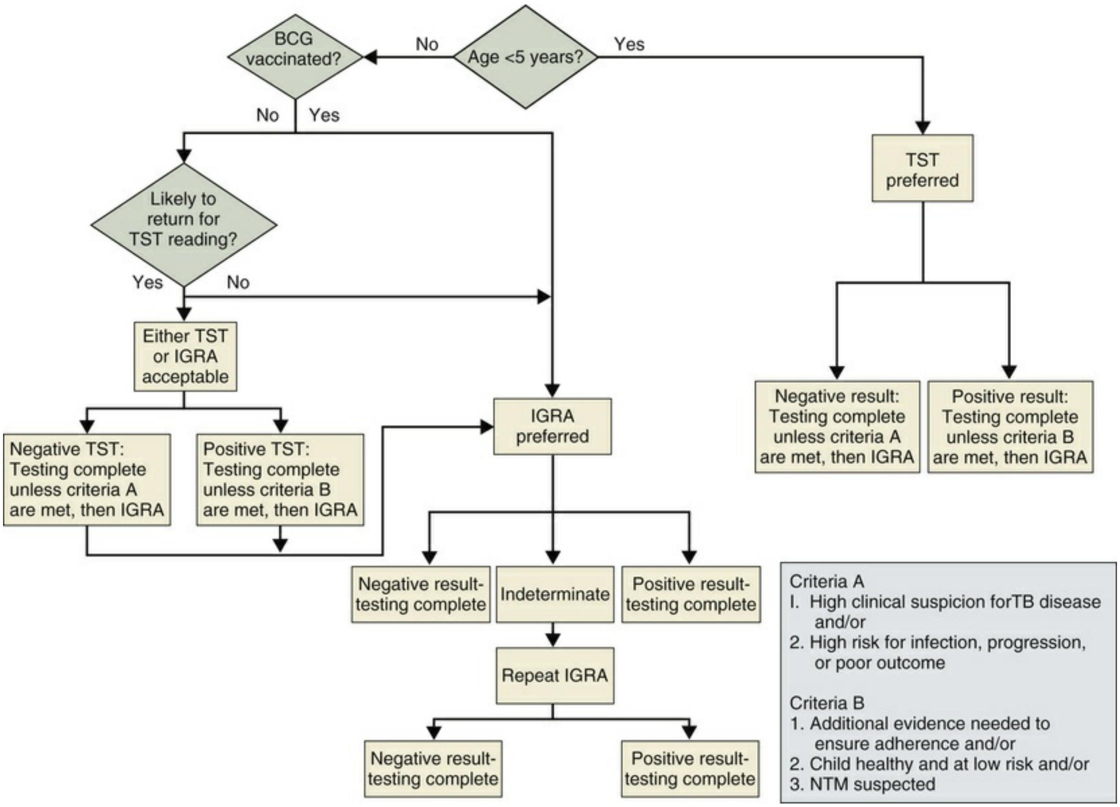
The lack of a gold standard for the detection of TB infection complicates studies of diagnostic accuracy,[98] many of which have employed surrogate measures of infection to serve as the reference standard for TB infection.[96] The association between IGRA positivity and the presence of TB exposure is well described in low-burden countries.[99–101] Results from high-burden countries examining IGRA positivity and the presence of TB exposure are conflicting and demonstrate both advantages of the T.SPOT[102] and no difference in T.SPOT performance compared with TST and QFT.[103] A few key studies have illustrated that exposure may be quantified to support direct comparison of tests of TB infection.[100,102–105] The largest of these studies, including over 1300 children, demonstrated that IGRAs were more strongly associated with quantified TB exposure than the TST.[105] Pooled analysis of studies employing a measure of TB exposure also demonstrates that positive IGRA results are more strongly correlated with quantified TB exposure than the TST results.[96]

There is limited and conflicting evidence regarding IGRA use in young or impoverished children. Studies have demonstrated variable association between indeterminate IGRA results and young age, with some studies showing an association[106–111] and others showing no association.[103,105,112,113] A seminal study of European immigrant children found that indeterminate IGRA results were more frequent among young children but occurred at clinically insignificant rates of 1.8% and 1.6 % for the QFT and T.SPOT, respectively.[111] Most studies have reported indeterminate rates less than 10%.[96] Emerging evidence further demonstrates that a number of factors related to poverty (malnourishment,[105,113,114] micronutrient deficiency[115] and helminth infection)[116,117] may lead to diminished IGRA sensitivity.

Limited data are available regarding IGRA performance in immune-compromised HIV-infected children, in whom the performance of the TST is impaired.[118–120] Two studies suggest that test failures described as indeterminate or invalid results are common among pediatric oncology patients.[121,122] Two studies have shown a noncommercial IFN-$\gamma$ ELISPOT assay to have higher sensitivity for detecting TB infection compared with the TST in HIV-infected children.[118,123] A comparison of the QFT–gold assay and the TST for the detection of TB infection in 36 young HIV-infected children with culture-confirmed TB disease found comparable sensitivity in children with CD4+ cell counts below 200/mL; unfortunately indeterminate QFT-gold results were reported in 25% of children tested.[124] In a head-to-head comparison among 130 HIV-infected and 120 HIV-uninfected children, the TST and IGRAs performed similarly for the detection of TB infection in well-nourished HIV-uninfected children, but test performance was differentially affected by chronic malnutrition, HIV infection and age.[113] In a study of over 1300 children, indeterminate QFT results were more frequent in HIV-infected (4.7%) than HIV-uninfected children (1.9%), while T.SPOT invalid results were rare (0.2%) and were not affected by HIV infection.[105] Conversion, reversion and operational measures were not associated with HIV status. Among HIV-infected children, test sensitivities declined as malnutrition worsened. As a conclusion from the available evidence, clinicians should take age, nutritional status, and HIV status into consideration in interpreting IGRAs.

Both the TST and IGRAs have limitations, but use of the tests in targeted populations with increased risk of TB infection or TB disease maximizes the impact of testing. IGRAs are commonly used in children living in upper-income, low-burden countries and have influenced clinical decision making.[123] National guidelines continue to change and vary dramatically among countries in light of rapidly emerging evidence. Pragmatic approaches to the use of IGRAs and TST have emerged through clinical practice and are emerging in formal guidelines.[125]

The purpose of the TST and IGRAs is to determine whether the person is infected with *M. tuberculosis,* which can serve as a useful tool in the diagnosis of TB, and guide subsequent care for infection or disease. Attributes of the child and the purpose of the testing should inform the choice of which diagnostic test to use (Fig. 29.15). Per the American Academy of Pediatrics (AAP), “Only children who have risk of TB exposure, underlying health conditions that require immune suppression, or suspected TB disease should be tested for TB infection in TB low-burden settings.”[125] In low-risk, BCG-vaccinated or NTM-exposed children in whom the TST will result in a considerable number of false-positive results, high specificity is desired, making the IGRAs preferable. In young or immune-compromised children with significant risk of TB progression following TB infection, testing strategies should optimize sensitivity. Although it may compromise specificity of the testing strategy, both an IGRA and a TST should be performed in a child with a high suspicion of TB disease or a high risk of progression to TB disease. In these instances, a positive result with either the TST or IGRA should be considered evidence of TB infection. Although this approach may result in overtreatment, the benefits of avoiding disease progression generally outweigh the risk of overtreatment, particularly since children tolerate treatment of TB infection with few side effects.



BCG vaccinated?
No
Age <5 years?
Yes
No
Yes
TST preferred
Likely to return for TST reading?
Yes
No
Either TST or IGRA acceptable
IGRA preferred
Negative result: Testing complete unless criteria A are met, then IGRA
Positive result: Testing complete unless criteria B are met, then IGRA
Negative TST: Testing complete unless criteria A are met, then IGRA
Positive TST: Testing complete unless criteria B are met, then IGRA
Negative result-testing complete
Indeterminate
Positive result-testing complete
Repeat IGRA
Negative result-testing complete
Positive result-testing complete
Criteria A
1. High clinical suspicion for TB disease and/or
2. High risk for infection, progression, or poor outcome
Criteria B
1. Additional evidence needed to ensure adherence and/or
2. Child healthy and at low risk and/or
3. NTM suspected

**FIG. 29.15** An algorithm for the use of tuberculin skin test (TST) and interferon-γ release assays (IGRAs) in children with risk of tuberculosis (TB) infection in low-burden settings. *BCG,* Bacillus Calmette-Guérin; *NTM,* nontuberculous mycobacteria. (Reproduced with permission from the American Academy of Pediatrics. *Pediatrics.* 2014;134(6):e1770.)

IGRAs offer several pragmatic advantages compared with the TST (Table 29.2). Use of *M. tuberculosis*–specific antigens improves specificity and decreases the chance of false-positive responses, particularly in young BCG-vaccinated children. Use of internal positive controls assesses anergy, which can be useful in immune-compromised and young children. Because IGRAs do not require a second visit to measure the response, they afford an advantage in testing patients who may have difficulty returning, such as emergency department patients, migrants, and homeless individuals. Although the direct cost of IGRAs is greater than that of the TST, evidence from studies of adults suggests that IGRAs are cost-effective in certain populations and in high-income settings by decreasing the number of false-positive results and reducing the subsequent evaluation and treatment of patients.[126–129] However, the WHO has recommended against the use of IGRAs in low- and middle-income countries for several reasons, including but not limited to a lack of evidence of on their performance in high-burden, low-income countries and the increased cost and technical skill required as compared to the TST.[130]

## Table 29.2

**Comparison of the Tuberculin Skin Test and Interferon-Gamma Release Assay**

| Consideration | TST | IGRA |
|---|---|---|
| Sampling | Intradermal injection | Blood draw |
| Patient visits required | Two | One |
| BCG cross-reactivity | Yes | No |
| NTM cross-reactivity | Yes | Infrequent[a] |
| Boosting associated with repeat testing | Yes | No |
| Population specific interpretation | Yes | No |
| Internal controls for anergy | No | Yes |
| Subject to human variability | Yes | No |
| Subject to laboratory error | No | Yes |
| Requires trained clinical staff | Yes | No |
| Requires trained laboratory staff | No | Yes |
| Relies on host immune function | Yes | Yes |
| Distinguishes TB infection from disease | No | No |
| Predicts progression from TB infection to disease | No | No |
| Distinguishes remote versus recent infection | No | No |
| Monitors treatment efficacy | No | No |

[a] IGRA positivity results from infection with the following organisms thereby decreasing test specificity: *Mycobacterium marinum, M. kansasii, M. szulgai* and *M. flavescans.*

*BCG,* Bacillus Calmette-Guérin; *IGRA,* interferon-gamma release assay; *NTM,* nontuberculous mycobacteria; *TB,* tuberculosis; *TST,* tuberculin skin test.

# Laboratory Diagnosis

Careful attention to the details of specimen collection and handling can optimize the isolation and identification of *M. tuberculosis.* A variety of specimens can be collected, including sputum, induced sputum, gastric aspirates, bronchial washings, bronchoalveolar lavage, transbronchial biopsy, urine, blood, tissue, cerebrospinal fluid and other body fluids.[131,132] Because children cannot easily produce sputum, gastric aspirates are frequently obtained. Optimal collection of gastric aspirates usually entails hospitalization to acquire about 50 mL of early-morning gastric contents after the child has fasted for at least 8–10 hours and preferably while he or she is still in bed.[133] Alternatively, trained public health nurses may perform this procedure in the home or clinic. *M. tuberculosis* may be recovered from gastric aspirates in roughly 40% of children with radiographic evidence of significant pulmonary disease.[134] Because many specimens contain an abundance of bacteria other than mycobacteria, specimens should be collected in a sterile fashion and held under conditions that minimize the growth of contaminating organisms.

In addition to gastric aspiration, sputum induction is a means of sample collection. In this process, a child is treated first with an inhaled beta agonist followed by hypertonic saline. As the child begins coughing, the practitioner suctions the child's mouth and throat to obtain the specimen. Sputum induction offers advantages as it can easily be performed in outpatient settings and only requires 3 hours of fasting as opposed to overnight fasting, which is considered optimal for gastric aspiration. In studies from Cape Town, sputum induction has yielded more positive cultures than gastric aspiration—51 of 250 (20%) versus 38 of 250 (15%)—with yield improving with the sampling of multiple specimens.[135]

The yield of any diagnostic test is increased if adequate specimens are obtained. In addition, yield increases for both gastric aspirates and induced sputum if multiple specimens are obtained. However, obtaining multiple specimens can be a difficult endeavor in outpatient settings, where children and their caregivers may have to travel far to access care. Both procedures require frequent training of health care workers and availability of necessary supplies to promote their use, which is often an obstacle in high-burden settings. Despite ongoing academic debate regarding the preferred sputum collection technique, providers should be supported to perform the procedure that they are most comfortable with, as this will likely lead to the greatest number of specimens being collected and ultimately improve diagnostic yield. Videos are available from the Francis Curry TB Center and Medecins Sans Frontieres South Africa to demonstrate how both gastric aspirates (https://www.youtube.com/watch?v=21Rjk2E-Lsc) and induced sputum (https://www.youtube.com/watch?v=sbGITrNP8j8) are obtained.

Diagnostic tests for TB disease either detect the presence of *M. tuberculosis* in a clinical sample or demonstrate a host response to the organism. Methods for diagnosis of TB are summarized in Table 29.3. Tests of infection, either IGRA or TST, can help clinicians who are considering a diagnosis of TB disease. If either test of infection is positive, it increases the likelihood that a child's symptoms are caused by *M. tuberculosis*, but as tests of infection can be negative during disease, a clinical index of suspicion should have more weight than a negative test of disease.

## Table 29.3

**Summary of Laboratory Methods for the Diagnosis of Tuberculosis**

| Identification Method | Test System | Use |
|---|---|---|
| Culture | Conventional media (Lowenstein Jensen, Middlebrook agars)<br>Colony morphology (3–5 weeks)<br>Biochemical tests | Preliminary identification<br>Species identification |
| Microscopic-observation drug-susceptibility (MODS) | Positive growth (1–2 weeks) | Identification and drug susceptibility<br>Easy, inexpensive, highly sensitive |
| Radiometric methods | Positive growth index (5–14 days) | Differentiates *Mycobacterium tuberculosis* from nontuberculosis mycobacterial species |
| Chromatography | HPLC mycolic acid profile<br>Gas chromatography–fatty acid profile | Speciates all common mycobacteria |
| DNA probes | Gen-Probe<br>ACCUPROBE<br>Syngene SNAP probes | Identifies *M. tuberculosis* complex, *M. avium, M. intracellulare-avium* complex, *M. kansasii, M. gordonae*<br>Identifies *M. tuberculosis* complex, *M. avium* complex |
| Rapid direct tests<br>Direct smear | Acid-fast or fluorochrome stains | Easy, inexpensive, moderately sensitive |

| | | |
|---|---|---|
| Nucleic acid detection | PCR amplification<br>Line probe assays | Moderately sensitive, highly specific, technically complex |
| Cartridge-based nucleic acid detection | GeneXpert | Highly specific, moderately sensitive, easy performance but high initial cost |

*DNA*, Deoxyribonucleic acid; *EIA*, enzyme immunoassay; *HPLC*, high-performance liquid chromatography; *PCR*, polymerase chain reaction.

## Staining and Microscopic Examination

Acid-fast staining and microscopic examination are the easiest, quickest, and least expensive diagnostic procedures. Yield of microscopy is dependent on stain selection because the auramine-rhodamine fluorescent stain is more sensitive than the traditional Kinyoun or Ziehl–Neelsen stains. However, these methods can provide physicians with only preliminary confirmation of the diagnosis because of the inability to differentiate between *M. tuberculosis* and NTM. Additionally, there must be 5000–10,000 bacilli present per milliliter of specimen to allow detection of the bacteria in stained smears, resulting in low sensitivity in children. Acid-fast staining of gastric aspirates and sputum is positive in fewer than 10% of children with pulmonary TB.

## Culture

Culture is the most important laboratory test for the diagnosis and management of TB. A positive culture may result from as few as 10 organisms per milliliter of specimen. Growth of bacilli is necessary for precise speciation and DST. Genotyping of the organism may be useful to identify epidemiologic links. Unfortunately bacteriologic confirmation of TB in children is generally poor. For example, in the United States from 1997 to 2007, over 70% of adult pulmonary TB cases had a positive culture, compared with 45% in children.[136] In three studies evaluating the role of bronchoscopy, only 13%–62% of cultures in children with pulmonary TB were positive.[134,137,138] The yield from gastric aspirates was higher in these studies. Bronchoscopy can be useful to define anatomy or clarify the diagnosis, but it cannot be recommended solely to collect culture specimens in children.

Reliance on detection of *M. tuberculosis* using available methods will lead to misdiagnosis of the majority of cases of childhood pulmonary TB. Even in developed countries, the gold standard for diagnosis of childhood TB is a triad of (1) an abnormal chest radiograph and/or clinical findings consistent with TB, (2) a positive TST or IGRA result and (3) a history of contact with an infectious TB case within the past year. If the results of DST on the organism isolated from the contact case are available, obtaining a culture from the child adds little sensitivity or specificity to the diagnosis if the triad is present.[51,58]

As noted in the section on mycobacteriology, specimens can be isolated on either solid or liquid media, taking 7–10 days for growth in liquid media and 3–6 weeks for growth on solid media. Standard concentrations of antitubercular drugs can be added to the media to provide DST. A certain amount of growth in media containing antitubercular therapy versus controls indicates phenotypic resistance.

The microscopic-observation drug-susceptibility (MODS) assay is a variation of traditional DST, where the organism is inoculated into several wells containing concentrations of antitubercular drugs in addition to a control well. The wells are examined daily by inverted light microscopy to visualize cord formation, which indicates *M. tuberculosis* growth. The growth in wells with antitubercular drugs indicates resistance. This assay has been shown to perform better than traditional culture methods in two settings. In Peru, two cohorts showed that MODS detected more TB cases (87%–91%) versus traditional culture methods (55%–59%).[139] In Vietnam, MODS performed better than smear (46% vs. 8.8%) and culture (46% vs. 38.9%), even on nonsputum samples.[140] MODS is endorsed by the WHO for use at reference laboratories.[141]

## DNA Methodologies

DNA probe methods use nucleic acid hybridization with specifically labeled sequences to rapidly detect complementary sequences in the test sample. Various systems are commercially available. Although the *M. tuberculosis* complex probe tests have been 99%–100% specific, the dependence of these methods on large numbers of bacilli means that they can be used only in the laboratory on cultured organisms.[142]

Direct detection of the DNA of *M. tuberculosis* in clinical samples has been performed using nucleic acid amplification, most often utilizing the polymerase chain reaction (PCR). Most techniques have used the mycobacterial insertion element IS6110 as the DNA marker for *M. tuberculosis* complex organisms.[143] Evaluation of traditional PCR for childhood TB has been limited. As compared with the clinical diagnosis of pulmonary TB in children, the sensitivity of PCR on sputum or gastric aspirates has varied from 25% to 83%, and the specificity has varied from 80% to 100%.[144–146] A negative PCR never eliminates TB as a diagnostic possibility, and a positive result does not completely confirm it.

However, in 2010, the WHO endorsed the use of a newer PCR method, the GeneXpert MTB/RIF assay (Xpert) (Cepheid, Sunnyvale, California). The WHO commissioned its use in resource-limited settings for both adult and pediatric specimens as well as pulmonary and extrapulmonary specimens.[147] Xpert is a cartridge-based PCR platform that detects the presence of *M. tuberculosis* DNA as well as the presence of mutations in *rpoB* gene, which confer resistance to RIF. A systematic review and meta-analysis of 15 pediatric studies that were performed across a wide range of settings showed no difference in the performance of Xpert between induced sputum, expectorated sputum, or gastric lavage. The sensitivity of Xpert ranged widely in all the studies, but the pooled sensitivity was 66%, versus the 28% sensitivity of smear microscopy. In contrast, the specificity of Xpert had little variation between the studies and yielded a pooled specificity of 98%.[148] Xpert's limit of detection is 131 CFU/mL, as compared with smear's 5000–10,000 CFU/mL and culture's 10 CFU/mL.[149–151] Given the paucibacillary nature of childhood TB and the limited specimen volumes children can produce, Xpert's limits of detection are not able to capture all cases of childhood TB, and it does not replace the use of culture or clinical diagnosis.

Xpert also provides information regarding potential RIF resistance. In studies in Cape Town, Xpert has been shown to have good correlation with DST, with one study showing the sensitivity and specificity for RIF resistance to be 83.3% and 99.1%, respectively.[152–154] However, the presence or absence of the *rpoB* gene mutation does not equal phenotypic resistance or susceptibility, as not all RIF resistance is related to this specific gene mutation.[155] Therefore Xpert's RIF resistance results should be used only to evaluate potential drug resistance in a timely manner and should always be confirmed with phenotypic testing. Other diagnostic measures should be used to evaluate the full drug susceptibility profile of the organism.

In addition to its specificity and improved sensitivity versus microscopy, Xpert has further advantages over other nucleic acid detection techniques. The methodology is user-friendly and does not require extensive training, which allows it to be potentially used in decentralized clinics. Furthermore, the processing time for a specimen is only 2 hours once the specimen has reached the laboratory, thus decreasing wait times for patient results substantially. Unfortunately, in many TB high-burden settings, the health systems do not have the capacity to relay Xpert results to the clinician immediately, which negates the advantages that Xpert was designed to provide.

### Line Probe Assays

Newer molecular assays, termed line probe assays (LPAs), are also available in some settings; these are PCR tests that detect mutations in the genes that confer resistance. The DNA is amplified and hybridized to probes that bind to colorimetric strips. The operator then interprets the resistance profile from the pattern of colorization. LPAs are endorsed by the WHO and are used increasingly around the world, but limitations are noted on their sensitivities, specifically among the injectable agents used as second-line drugs used to treat resistant TB.[156] Furthermore, because they indicate the presence of genetic mutations, they do not indicate the phenotypic expression of these mutations.

## Treatment

Each of the distinct clinical stages of disease caused by *M. tuberculosis* has a distinct treatment regimen, as further described in the following sections and illustrated in Table 29.4.

## Table 29.4

**Preventive Regimens for Tuberculosis Infection in Children**

| Resistance Pattern of Source Case | Antimycobacterial Agent Dosage and Duration | Comments |
|---|---|---|
| INH-susceptible or unknown | 1 INH, 10–20 mg/kg as single daily dose × 9 months (maximum 300 mg per dose)<br>2 INH, 20–40 mg/kg/dose twice weekly × 9 months (maximum, 900 mg per dose)<br>3 INH + rifamycin (3HP):<br>INH 15 mg/kg (max dose 900 mg)<br>Rifapentine<br>10.0–14.0 kg: 300 mg<br>14.1–25.0 kg: 450 mg<br>25.1–32.0 kg: 600 mg<br>32.1–49.9 kg: 750 mg<br>>50 kg: 900 mg<br>once weekly × 12 weeks<br>4 INH 10 mg/kg + RIF 10 mg/kg as single daily dose × 3 months (maximum, 900 mg INH + 600 mg RIF) | Optimal duration for children is debated<br>CDC and AAP recommend 9-month intermittent schedule should be given only by DOT |
| INH-resistant or INH not tolerated | RIF, 10–20 mg/kg/dose as single daily dose × 4 months (maximum, 600 mg per dose) | |
| MDR-TB (resistant to INH and RIF) | Guided by susceptibility testing on a child or source case isolate | Should be provided in consultation with an expert<br>DOT strongly recommended |

*AAP*, American Academy of Pediatrics; *CDC*, Centers for Disease Control and Prevention; *DOT*, directly observed therapy; *INH*, isoniazid; *MDR-TB*, multidrug-resistant tuberculosis; *RIF*, rifampin.

# Treatment of Tuberculosis Exposure

If a child has been exposed to an individual with potentially contagious TB, there is the possibility that child could have become infected with the organism. Children take up to 3 months to develop an immune response sufficient to produce a positive TST or IGRA result,[157] and children younger than 5 years of age may develop severe disease before these tests become positive.[158] Because of this risk, in low-burden settings with active contact tracing, children under the age of 5 with a known or suspected exposure to an adult with potentially contagious TB, should have an initial test of infection performed at the time of presentation. If the initial test of infection is negative, then the child should receive treatment with INH, as he or she may have already acquired infection but not yet developed an immune response to a test of infection. Children younger than 5 are at increased risk of developing potentially severe disease in the meantime; thus INH offers critical protection for this at-risk population. A test of infection should then be repeated 8–10 weeks after the child is no longer exposed to TB. If the result of the second test of infection is negative, therapy may be discontinued. If the result of the second test of infection is positive, a full course of treatment for TB infection should be given, as detailed in a later section.

## Isoniazid Preventative Therapy

In areas where tests of infection are not readily available, the WHO recommends initiation of Isoniazid Preventative Therapy (IPT) in HIV-uninfected children under the age of 5 who have been in contact with an individual with contagious TB. These children must first be evaluated for disease with at minimum a symptom screen assessing for fever, cough and weight loss. If they lack any signs or symptoms of TB disease, they are given daily INH for 6 months. Given the low rate of side effects in this age group and the resource constraints of the setting, tests of infection are not used but rather infection is presumed, given the proximity of the child to the individual with contagious TB. Treatment is typically with INH for 6 months in high-burden settings.

Another form of IPT is specific for HIV-infected individuals regardless of age. In high-burden settings where presumably an HIV-infected individual is continually exposed to TB, the WHO has recommended that HIV-infected individuals be screened regularly for TB symptoms—including fever, cough, weight loss/poor weight gain, and night sweats—and individuals who have a negative TB screen be given 36 months of INH to treat potential TB infection and prevent future TB disease and transmission.[159]

Despite international and national guidelines, recommending IPT in children, delivery and monitoring of IPT to children remains poor. Existing data demonstrate that poor IPT delivery is due to missed opportunities for IPT,[27,160,161] poor uptake and adherence,[162,163] and limited administrative systems to support IPT delivery.[164] In order to improve IPT delivery in TB high-burden settings, IPT must become a core intervention of both TB and HIV control programs that is supported by regionally appropriate tools, implementation, monitoring, and evaluation systems.

## Treatment of Tuberculosis Infection

Asymptomatic TB infection is the most common presentation of children exposed to TB. These children have a reactive TST or IGRA, normal chest radiograph, no clinical evidence of TB disease, and presumed infection with small numbers of viable tubercle bacilli. Children with TB infection should receive treatment for the following reasons: (1) infants and children less than 5 years of age have been infected recently and are immunologically immature, so risk for progression to disease is high; (2) risk for severe disease, including meningitis and disseminated disease, is inversely related to age; (3) children with TB infection have more years at risk for the development of disease later in life; (4) children with TB infection become adults who may transmit organisms if they develop disease; and (5) the risk of developing disease is higher than the risk of developing significant adverse reactions from treatment for TB infection.[125]

Several large clinical trials have demonstrated the efficacy of INH to reduce the risk for TB in children with TB infection. In 1958, the US Public Health Service (USPHS) conducted a randomized trial to prevent TB in boarding schools in Alaska.[165] Two dosing regimens of INH were studied, 1.25 mg/kg per day versus 5 mg/kg per day given for 6 months to 1701 attendees 5–20 years of age for either 5 days per week or daily. In 10 years of follow-up, participants who received the higher dose of INH had significantly less progression to disease (1.9%), 10 of 513, than participants receiving the lower dose (5.8%), 31 of 536. The study also demonstrated that an intermittent therapy course (5 days per week) was efficacious. Additional randomized controlled trials completed by the USPHS in the 1950s and 1960s found the protective efficacy of INH treatment of TB infection to be approximately 90% when analysis was restricted to adherent participants.[166] Secondary analysis of two USPHS household contact studies has suggested that the efficacy of

INH treatment of TB infection plateaus at 9–10 months of therapy.[167] Similarly, in a study among the Inuit in Alaska, a second year of INH treatment did not result in additional benefit beyond that conferred by the first year of treatment.[168,169] Although the International Union against Tuberculosis and Lung Disease (IUATLD) evaluated the efficacy of various durations of INH therapy in adults with TB infection, similar studies have not been conducted in children. There have also been no comparison studies between 6 and 9 months of INH. In the IUATLD trial, individuals who completed 12 months of INH therapy with good adherence had a reduced TB incidence by 93%, compared with a 69% reduction if a 6-month INH course was completed with good adherence.[170] Comparing the overall benefit regardless of adherence showed a more equivocal comparison between 6 and 12 months of therapy.[132] In addition, cost-effectiveness studies have suggested no increased benefit between 6 and 12 months of therapy.[171] Difficulties with adherence as well as the cost/benefit ratio have led the WHO to recommend 6 months of INH therapy for TB infection. However, the current AAP recommendation for treatment of TB infection in children is 9 months of INH given either daily (10–15 mg/kg, maximum 300 mg usually under self-supervised administration) or twice weekly (20–30 mg/kg, maximum 900 mg) under directly observed therapy (DOT).

RIF has been used for the treatment of TB infection in children and adolescents when INH was not tolerated or the child was exposed to an individual with an INH-resistant, RIF-susceptible isolate. A daily 4-month-long course is considered an alternative treatment to INH in the United States.[172] In addition, a new regimen consisting of INH and a long-acting rifamycin called rifapentine is available in some areas. This regimen is given once weekly for 12 weeks. It has been shown to be as effective as and safer than 9 months of daily self-administered INH. This regimen is well tolerated in teens and older children. Its use is limited in younger children owing to the lack of a liquid formulation and pharmacokinetic data for children under the age of 2 years.[173]

In some areas, a 3-month regimen of daily INH and RIF in combination is used to treat TB infection. This regimen has been shown in several studies to be as effective and as safe as other regimens, although randomized controlled studies in children are lacking.[174] The majority of a data supporting this regimen come from British observational studies, which show a reduced incidence of childhood TB disease on daily INH and RIF.[175,176]

Treatment of TB infection should be tailored according to host immune factors, drug susceptibility, tolerance, and compliance (see Table 29.4). Any treatment can be used in HIV-infected children with documented evidence of TB infection, although care should be taken to avoid drug interactions between RIF/rifamycin and the protease inhibitors used in highly active retroviral therapy (HAART). Treatment of infection with an organism must be individualized and should be delivered via DOT, if resources are available. In instances where the MDR isolate is susceptible to fluoroquinolones, such as levofloxacin or moxifloxacin, these agents can be used to treat infection. This can be given alone or in combination with another agent to which the organism is susceptible, often ethionamide or ethambutol. However, the combination of pyrazinamide and a fluoroquinolone should be avoided owing to an increased risk of adverse events. There are no studies indicating the exact duration of treatment, but daily administration for 6 months is recommended. Any child exposed to MDR-TB should be followed closely for 18 months, whether treated or not, in order to identify disease quickly and initiate appropriate therapy in order to avoid poor outcomes.[177]

Providers should follow otherwise healthy children on treatment for TB infection with periodic physical exams. Laboratory investigations are required only if children experience side effects of the medications. Both INH and RIF can cause elevated transaminases, usually associated with abdominal pain and vomiting. The fluoroquinolones tend to be well tolerated in children but have been associated with transient arthralgias.

## Tuberculosis Disease

### Principles of Treatment

Treatment of TB disease is designed to prevent the complications of disease in the host and the development of drug resistance in the organism. Antitubercular agents should be bactericidal and effective against intracellular and extracellular organisms. Three or more drugs are used empirically for initial therapy and adjusted when DST is available. Initial use of a single agent will select for emergence of a dominantly resistant population of bacilli in individuals with TB disease. Therapy should be provided for extended periods via DOT to ensure compliance. Length of therapy is dependent on the site of infection.

## Pulmonary Tuberculosis

The first-line drugs used to treat TB disease in children are shown in Table 29.5. Many therapeutic trials have been reported in children with pulmonary TB. A 6-month regimen consisting of INH and RIF was effective in some patients with isolated hilar adenopathy and without drug-resistant organisms.[178] Limited data are available to support a 6-month, INH-RIF regimen for the treatment of drug-susceptible pulmonary TB.[179] At least a dozen studies have examined the efficacy of 6-month regimens consisting of three or more drugs in children with pulmonary TB. The most common regimen studied consisted of INH and RIF, supplemented with pyrazinamide during the first 2 months. Most trials used daily therapy for the first 2 months, followed by daily or twice-weekly therapy to complete 6 months. In these trials, the overall success rate was greater than 95% for cure and 99% for significant improvement during a 2-year follow-up.

### Table 29.5

### Commonly Used Drugs for the Treatment of Tuberculosis in Children

| Drug | Dosage Forms | Daily Dose (mg/kg) | Twice-Weekly Dose (mg/kg Per Day | Maximum Dose |
|---|---|---|---|---|
| Ethambutol | Tablets: 100 mg, 400 mg | 20 | 50 | Daily: 1 g<br>Twice weekly: 2.5 g |
| Isoniazid[a,b] | Scored tablets: 100 mg, 300 mg<br>Syrup: 10 mg/mL | 10–15 | 20–30 | Daily: 300 mg<br>Twice weekly: 900 mg |
| Pyrazinamide | Scored tablets: 500 mg | 20–40 | 50 | 2 g |
| Rifampin[a] | Capsules: 150 mg, | 10–20 | 10–20 | Daily: 600 |

| | | | | |
|---|---|---|---|---|
| | 300 mg<br>Formulated in syrup from capsules | | | mg<br>Twice weekly: 900 mg |

[a]Rifamate is a capsule containing 150 mg of isoniazid and 300 mg of rifampin. Two capsules provide the usual adult (>50 kg body weight daily doses of each drug).

[b]Most experts advise against the use of isoniazid syrup because of its instability and a high rate of gastrointestinal adverse reactions (diarrhea, cramps).

*IM,* Intramuscular.

Although current guidelines recommend that all patients be started on a four-drug regimen,[180] a three-drug regimen may be used in children exposed to a source case with pan-susceptible TB. Hence, in children with suspected INH-susceptible pulmonary TB, the recommended treatment is a 6-month regimen consisting of INH and RIF, supplemented during the first 2 months with pyrazinamide. The first 2 months of multidrug therapy are frequently referred to as the *intensive phase.* Daily administration of the regimen during the first 2 weeks to 2 months may be followed by at minimum twice-weekly therapy to complete 6 months, a period referred to as the *continuation phase.* All treatment for TB disease should be administered by DOT unless there is a compelling reason to avoid it.

In children or adolescents with adult-type pulmonary TB or epidemiologic circumstances suggesting an increased risk for infection with an organism that is resistant to INH, the American Thoracic Society (ATS) recommends an initial 2-month treatment phase consisting of daily administration of four drugs: INH, RIF, pyrazinamide, and ethambutol. This initial treatment is followed by 4 months of INH and RIF twice-weekly therapy administered under DOT if the organism is susceptible to both drugs.[180] Although there have been concerns about the use of ethambutol because it can cause optic neuritis, which is difficult to detect in children, this adverse effect is extraordinarily rare in children and should not preclude the use of ethambutol.

The optimal treatment of pulmonary TB in children and adolescents with HIV infection is unknown. In HIV-infected children with TB disease who received three to four drugs in the initiation phase followed by INH and RIF in the continuation phase for 6 months, a recurrence risk of 13% has been reported despite good adherence.[181] The AAP and ATS recommend initial therapy that should consist of four drugs for the first 2 months with a total duration of therapy that can go up to 9 months for HIV-infected children not on antiretroviral therapy.[180] The WHO recommends that TB in HIV-infected children should be treated with a 6-month regimen similar to the treatment of HIV-uninfected children, but treatment should not be delivered using intermittent schedules.[182,183] In HIV-infected adults with TB disease, prolonged TB treatment duration[184–186] and use of HAART.[186–189] reduce the risk of TB recurrence. In children, reduced TB incidence rates in those on HAART compared with the rates of those not on HAART are seen in retrospective and observational cohort studies.[190,191] The optimal timing for initiating HAART in HIV-infected children with TB disease is not known, but the WHO recommends initiation of HAART within 2–6 weeks of starting TB therapy.[182] Newer recommendations from the ATS, Centers for Disease Control and Prevention, and Infectious Disease Society of America recommend initiating HAART at the same time as TB therapy, as there is evidence of improved outcomes. In treating HIV-infected children with TB disease, a number of special issues must be considered, including drug-drug interactions, immune reconstitution inflammatory syndrome (IRIS), and drug-resistant TB.[192] See Chapter 66 for a full discussion of ART regimens options to be used in childhood TB.

## Extrapulmonary Tuberculosis

Controlled therapy trials have not been reported for children with extrapulmonary TB. In general, recommended treatment for extrapulmonary TB is the same as for pulmonary TB. Osteotuberculosis and TB meningitis are exceptions. Recommended treatment of drug-susceptible osteotuberculosis includes 9–12 months of INH and RIF or 6 months of INH and RIF supplemented by two other drugs during the first 2 months of therapy. There are inadequate data to support any 6-month treatment regimen for TB meningitis.[193] Recommended regimens consist of the standard intensive phase regimen during the initial 2 months followed by 7–10 months of therapy with INH and RIF.

## Drug-Resistant Tuberculosis

The incidence of drug-resistant TB is increasing in the United States and the world because of poor patient adherence, the availability of some antituberculosis drugs in noncontrolled over-the-counter formulations, migration of at-risk people and poor medical management. In the United States, approximately 10% of *M. tuberculosis* isolates are resistant to at least one drug. Of the 480,000 cases of MDR-TB estimated by WHO to have occurred in the world in 2014, only about a quarter of these—123,000—were detected and reported. Of note, mathematical modeling predicts that 25,000–32,000 children fall ill to MDR-TB each year, suggesting an even greater reporting gap than that estimated by WHO.[21,22] Certain epidemiologic factors—recent immigration, homelessness in some communities, and history of previous antituberculosis therapy—correlate with drug resistance in adult patients. Drug-resistant cases are classified in categories based on DST of clinical isolates confirmed to be *M. tuberculosis:*

- **Monoresistance:** resistance to one first-line anti-TB drug only.
- **Polydrug resistance:** resistance to more than one first-line anti-TB drug (other than both INH and rifampicin).
- **MDR:** resistance to at least both INH and rifampicin.
- **Extensive drug resistance (XDR):** resistance to any fluoroquinolone and to at least one of three second-line injectable drugs (capreomycin, kanamycin, and amikacin, in addition to MDR).
- **Rifampicin resistance:** resistance to rifampicin detected using phenotypic or genotypic methods, with or without resistance to other anti-TB drugs. It includes any resistance to rifampicin, whether monoresistance, multidrug resistance, polydrug

resistance, or XDR.

Patterns of drug resistance in children tend to mirror those found in adult patients in the population.[194] Outbreaks of drug-resistant TB in children occurring at schools have been reported. Individual cases also have been recognized. Since it is difficult to isolate *M. tuberculosis* from children because of the paucibacillary nature of childhood TB, the determination of drug resistance in childhood TB is often inferred from the contact with contagious TB. Hence it is critically important to identify the adult source case that infected the child, as the drug susceptibility patterns of the culprit organism are required to determine an effective therapy regimen.

Therapy for drug-resistant TB is successful only when four to five drugs to which the strain of *M. tuberculosis* is susceptible, at least two of which are bactericidal, are given. If only one effective drug is given, secondary resistance will develop. The drugs used to treat MDR-TB are listed in Table 29.6. Treatment typically requires a backbone of (1) a fluoroquinolone [group A], (2) an injectable agent [group B], (3) at least two other second-line drugs with evidence of activity against the isolate [group C] and (4) whichever first-line drugs to which the isolate remains susceptible [group D1].[195] This should result in a regimen consisting of at least five agents. If this cannot be achieved because of the isolate's susceptibility profile, agents from D3 can be used until five agents compose the regimen.[195]

## Table 29.6

### Drugs Used to Treat Multidrug-Resistant *Mycobacterium Tuberculosis*

| Drug Group | Agents Within Group | Side Effects | Side-Effect Monitoring |
|---|---|---|---|
| Group A: Fluoroquinolones | Levofloxacin<br>Moxifloxacin<br>Gatifloxacin | Arthralgias/arthritis, GI disturbance, sleep disturbance, | Signs and symptoms |
| Group B: Second-line injectable agents | Amikacin<br>Kanamycin<br>Capreomycin<br>Streptomycin[a] | Pain at injection site, nephrotoxicity, ototoxicity | Monthly creatinine and potassium, monthly audiology |
| Group C: Other core second-line | Ethionamide/prothionamide | Hypothyroidism<br>GI upset | Monitor TSH, T4 at baseline and every 3 |

|  |  |  |  |  |
|---|---|---|---|---|
| agents |  |  |  | months |
|  |  | Cycloserine/terizidone | Neurologic and/or psychologic side effects | Monitor for signs and symptoms |
|  |  | Linezolid | Bone marrow suppression, optic neuritis, lactic acidosis | Blood counts at baseline, then monthly for the first 2 months, then then every 2 months × 2 then every 3 months |
|  |  | Clofazimine | Skin discoloration, dry skin, abdominal pain | Monitor for signs and symptoms |
| Group D: Add-on agents | D1 | Pyrazinamide | Hepatitis, arthritis | HIV-uninfected: no LFTs unless symptomatic<br>HIV-infected: LFTs at baseline, 6 months, and 15 months |
|  |  | Ethambutol | Optic neuritis | Color vision testing every month for first 6 months, followed by every 3 months thereafter |
|  |  | High-dose isoniazid | Hepatitis, peripheral neuropathy | HIV-uninfected: no LFTs unless symptomatic<br>HIV-infected: LFTs at baseline, 6 months, and 15 months |
|  | D2 | Bedaquiline/delamanid | QT prolongation | ECG at baseline, months 1 and 2, 4 and 6; every 3 months thereafter |
|  | D3 | p-aminosalycilic acid | Diarrhea | Monitor for signs and symptoms |
|  |  | Imipenem-cilastin[b] | Seizures | Monitor for signs and symptoms |
|  |  | Meropenem[b] |  |  |
|  |  | Amoxicillin-clavulanate[b] | Diarrhea | Monitor for signs and symptoms |
|  |  | Thioacetazone[c] | Stevens–Johnson syndrome in HIV-infected individuals | Monitor for signs and symptoms |

[a] Only to be used when other injectables cannot be used and the organism is susceptible to streptomycin.

[b] Must use amoxicillin-clavulanate with either imipenem-cilastin or meropenem.

[c] Thioacetazone can only be used in individuals who are not infected with HIV.

*ECG*, Electrocardiogram; *GI*, gastrointestinal; *HIV*, human immunodeficiency virus; *LFTs*, liver function tests; *TSH*, thyroid stimulating hormone.

Modified from the WHO 2016 Guidelines for Drug Resistant Tuberculosis.

The D2 agents, bedaquiline and delamanid, are the first new TB medications in 40 years. Bedaquiline, a dairylquinoline that inhibits mycobacterial adenosine triphosphate (ATP) synthase, was approved by the US Food and Drug Administration (FDA) and the European Medicines Association (EMA) in 2012. Delamanid, a nitroimidazole that inhibits synthesis of the mycobacterial cell wall, was approved by the EMA and the Japanese Regulatory Authority in 2014. Owing to limited to nonexistent pediatric data, the medications are not approved for use in children but may be used on a compassionate release basis when other options are unavailable.

Traditionally, MDR-TB in children has been treated for 18–24 months of therapy. In children with widespread disease or cavitary lung lesions, the treatment is an 18-month regimen with the injectable agents used for the first 4–6 months.[196] However, given newer evidence, the WHO has issued new MDR-TB guidelines stating that children with uncomplicated disease can complete a shorter 9-month treatment course composed of the “Bangladesh regimen,” named for the country where the shorter regimen was first investigated. It consists of an intensive phase of 4 months with gatifloxacin or moxifloxacin as well as kanamycin, prothionamide, clofazimine, ethambutol and high-dose INH. If an individual who is smear-positive is started on the regimen and fails to convert the smears before the end of the intensive phase, the guidelines recommend continuing the intensive phase until smear conversion occurs. After the intensive phase, the regimen consists of a 5-month-long continuation phase with the following medicines: gatifloxacin or moxifloxacin, clofazimine, ethambutol and pyrazinamide. Individuals should be excluded from this shorter-course regimen if they have had prior treatment with second-line TB drugs for the past month or have documented resistance to any medicines in the regimen.

The second-line TB drugs are associated with more side effects than the first-line therapy agents (see Table 29.6). In addition, few of these agents come in pediatric formulations, so children are frequently required to take halved and quartered tablets in order to obtain the correct dose. Potentially inaccurate dosing combined with a lack of pharmacokinetic studies of these drugs in children place children at risk for adverse events on treatment. Thus health care providers should closely monitor for adverse events, suggest mitigating factors, and make appropriate changes to therapy when able. In fact, the adverse events profile of the injectable agents, which includes nephrotoxicity and permanent hearing loss, has given rise to the newer WHO guidelines, which suggest that the harms associated with injectable agents may outweigh the potential benefits and that these agents may be excluded in children with mild disease.

The management of childhood MDR-TB is a complicated affair, and treatment guidelines change often as new evidence becomes available. The International Union against TB and Lung Disease provides a free interactive online module that covers the diagnosis and management of these patients at https://childhoodtb.theunion.org/courses/CTB2/en/intro. However, given the complexity of treatment and the rapidly changing knowledge base, a childhood TB expert should always be involved in the care of a child with MDR-TB.

## Adjunctive Therapy

Because INH competitively inhibits pyridoxine metabolism, resulting in a peripheral neuritis, pyridoxine (25–50 mg/day) is recommended for infants, children, and adolescents treated with INH who have nutritional deficiencies, symptomatic HIV infection, or diets low in milk or meat products and in breastfed infants. Corticosteroid administration is beneficial in the management of children when the host inflammatory reaction contributes significantly to tissue damage or impaired function. Administration of corticosteroids decreases mortality and morbidity in patients with TB meningitis by reducing vasculitis, inflammation, and intracranial pressure. Corticosteroid administration may significantly reduce compression of the tracheobronchial tree caused by hilar lymphadenopathy, reduce the alveolar-capillary block associated with miliary disease, to improve symptoms from pleural effusions, and to reduce symptoms and mortality from pericardial effusion.[180] Prednisone (1–2 mg/kg per day for 4–6 weeks) is most commonly employed.

## Follow-Up During Antituberculosis Therapy

The major goals of following children during treatment include promoting adherence, monitoring for toxicity and adverse effects of therapy and assessing clinical response. Patients should be evaluated monthly and receive only enough medication for the intervals between follow-up appointments. During all phases of treatment, clinicians should assess potential nonadherence with treatment. Children with missed appointments and questionable adherence should be referred to the responsible public health agency, which likely has programs incorporating incentives or behavioral modification.

Rates of adverse reactions caused by first-line antituberculosis medications are low in children. INH and RIF are associated with elevated serum alanine aminotransferase in less than 2% of children and rarely cause overt hepatitis. Elevated alanine aminotransferase levels are generally less than three times normal values, do not predict hepatotoxicity and are not an indication for discontinuing treatment. Routine biochemical monitoring is indicated only if the child has existing liver disease or is taking other potentially hepatotoxic drugs. It is preferable to educate caregivers relative to potential adverse events and clinical symptoms (abdominal pain, vomiting, jaundice necessitating medical evaluation) and immediate discontinuation of medication. Monitoring of adverse reactions in second-line drugs is shown in Table 29.6.

Frequent radiographic monitoring is not indicated. Because improvement of intrathoracic TB in children occurs slowly, chest radiographs are generally obtained at diagnosis. Some providers with available resources prefer to repeat a radiograph at completion of therapy to establish a new baseline for the patient. Radiographic resolution of hilar lymphadenopathy and associated pulmonary lesions may not occur for 2–3 years following treatment; a normal chest radiograph appearance is not necessary for completion of therapy. If resolution of radiographic abnormalities has not occurred by completion of therapy, radiographs may be obtained at 3- to 6-month intervals to assess continued improvement. Radiographs should also be repeated if the patient is not clinically improving.

# Control and Prevention

## Bacillus Calmette-Guérin Vaccination

BCG vaccines have been administered to nearly 4 billion people and have been routinely administered to newborns in most countries except the United States and the Netherlands. Nevertheless, the immune response to BCG and its mechanism of action are not well understood. Large clinical trials have shown the efficacy of BCG vaccination to range from 0% to 80%. A number of factors contribute to the heterogeneity of results from these trials, including eligibility criteria, strain of vaccine employed, vaccine administration, diagnostic criteria, disease surveillance, and environmental factors.[197] Although BCG does not prevent primary pulmonary TB, studies have demonstrated that BCG vaccination decreases the risk for developing severe forms of disease in very young children, including meningitis and miliary TB.[198,199] The clinical presentation of TB disease in older individuals who have received a BCG vaccination tends to be similar to that in nonimmunized persons.

BCG-induced immune responses in HIV-infected children are significantly lower compared with those in uninfected children.[200] Nevertheless, in the absence of antiretroviral therapy, HIV-infected infants have a significant risk of developing disseminated BCG disease, which is associated with a case fatality rate exceeding 75%.[201,202] Following initiation of antiretroviral therapy, 5%–10% of HIV-infected infants experience BCG IRIS.[203] The risk of serious BCG-related adverse events can be reduced by delaying BCG vaccination in HIV-exposed infants until their HIV status has been definitely established and in HIV-infected infants by rapid initiation of antiretroviral therapy.[204] Based on the high risk of disseminated BCG disease in HIV-infected infants, the WHO has recommended that infants with known HIV-infection should not receive BCG vaccination.[204] The practical feasibility of this recommendation has been questioned by TB experts in countries with high burdens of HIV and TB, where the feasibility of selectively deferred vaccination and potential disruption of general vaccination coverage is a concern.[205]

## Public Health Involvement

Childhood TB is a direct reflection of the incidence of adult TB within a community. Childhood TB usually represents recent transmission from an infectious adult or adolescent and is considered a sentinel event in public health. TB control programs should respond to a case of childhood TB by seeking to identify the source of infection and additional cases. Two distinct types of public health investigations exist. Contact investigations evaluate all contacts of an infectious adult or adolescent for TB disease or infection. Contact investigations have the highest yield for finding infected persons and are considered the cornerstone of reducing the incidence of TB disease. The WHO recommends contact investigation and treatment of exposed children, but this is often not performed in resource-limited settings. Some public health experts recommend that public health authorities develop estimates of numbers of children living in households with active TB cases. These estimates can then provide targets for the children investigated, which can help public health authorities plan financial and logistical resources that would allow for robust investigation and treatment.[206]

Source case investigations evaluate all contacts of a child with TB to identify an infectious adult or adolescent and other infected persons. Source case investigations are less successful because the child may have moved into the jurisdiction of the public health authorities and away from the source case. It is the public health authority's responsibility to ensure that all persons with suspected TB are identified and evaluated promptly and that appropriate treatment is prescribed and successfully completed. These responsibilities are accomplished through several activities, including epidemiologic surveillance and investigations, direct provision of diagnostic services and treatment and monitoring of treatment decisions and outcomes. The approach should be tailored for each patient to account for individual needs and ensure completion of therapy. DOT is the preferred, core management strategy to ensure adherence and involves providing the antituberculous drugs directly to the patient and watching that he or she swallows them.

# Nontuberculosis Mycobacterial Disease

*Stacey L. Martiniano MD, Jerry A. Nick MD, Charles L. Daley MD*

There is widespread agreement that detection of nontuberculous mycobacteria (NTM) is increasing worldwide within surveys of the general population[1–9] and among specific vulnerable disease groups.[10–12] The true incidence of disease caused by NTM is difficult to accurately track. Available data almost certainly underestimate the burden of infection due to the low clinical suspicion, the low sensitivity of available diagnostic techniques, and the lack of mandatory public health reporting of NTM infections. The most common presentation of NTM disease in children is cervical lymphadenitis, and skin and soft tissue infection. Pulmonary NTM disease in children occurs in the setting of preexisting lung disease, and is most often associated with cystic fibrosis (CF).[13] Disseminated disease may occur in the setting of immune compromise, often due to HIV/AIDS[13] or a variety of rare conditions.[14] The accurate diagnosis of pulmonary NTM disease can be challenging because of the limitations of available diagnostic tests and the common occurrence of transient or indolent infections in the absence of new or worsening symptoms.[15]

## Microbiology

The genus *Mycobacterium* consists of a diverse group of obligate aerobes that grow most successfully in tissues with high oxygen content, such as the lungs. These nonmotile, nonspore-forming, pleomorphic rods feature a cell wall rich in mycolic acids. The lipid-rich cell wall makes them impermeable to many stains unless the dyes are combined with phenol. Once stained, the cells resist decolorization with acidified organic solvents, resulting in their hallmark trait of "acid-fastness." This property is demonstrated with basic fuchsine stain techniques, such as the Ziehl-Neelsen and Kinyoun methods, or the more sensitive fluorochrome method using auramine and rhodamine stains.

More than 170 species of *Mycobacterium* have been described, with new species being identified each year.[16] Many NTM are nonpathogenic in humans, and others have been described to cause disease very rarely in case reports or small cases series of immunocompromised individuals.[17] NTM species are often categorized using the Runyon classification system based on rate of growth and pigmentation. The most commonly encountered NTM are among the "slow growers" and classified together as the *Mycobacterium avium* complex (MAC), which includes the species *M. avium, M. intracellulare, M. chimaera* among several other species and subspecies.[18] MAC is genetically close to the *Mycobacterium tuberculosis* complex, and is susceptible to several of the antibiotics effective in the treatment of tuberculosis. Another disease-causing slow growing NTM is *Mycobacterium kansasii.* Also of clinical significance is the *Mycobacterium abscessus* species complex (MABSC), which includes three subspecies, *M. abscessus, M. massiliense,* and *M. bolletii.* MABSC are classified as "rapid growers," and are genetically quite distinct from MAC.

Advances in diagnosis and treatment of NTM infection have lagged, in part, due to challenges relating to the culture, detection, and identification of the organisms. Methods developed for the isolation of *Mycobacterium tuberculosis* from clinical samples have been adapted for the isolation of NTM. Current recommendations are that both liquid and solid media are used for NTM culture with incubation for at least 6 weeks.[19] Isolation on solid media of slow-growing NTM takes 2–6 weeks; only the rapid growers reliably form visible colonies in less than 10 days. However, automated systems using liquid media allow detection of most species of mycobacteria more rapidly. Sensitivity is increased and the time for isolation is decreased by a larger specimen size and a higher bacterial burden. In the setting of CF, adequate sample decontamination to remove overgrowth of *Pseudomonas aeruginosa* and other coinfections is essential to permit culture-based detection of NTM.[20] Importantly, decontamination protocols can reduce NTM viability in samples, resulting in false negative results.[21] Current best practice for CF isolates consists of a two-step approach of (N-acetyl-L-cysteine–2% sodium hydroxide (NALC-NaOH) decontamination prior to mycobacterial culture with the addition of a second decontamination using 5% oxalic acid or 1% chlorhexidine to permit the recovery of NTM from persistently contaminated samples, albeit with reduced sensitivity.[20,22]

Traditional identification of NTM relies on statistical probabilities of a characteristic reaction pattern in a battery of biochemical tests. Molecular methods have now surpassed biochemical tests for NTM identification in many laboratories. These tests include line probe assays,[23] polymerase chain reaction (PCR) product restriction analysis,[24] and partial gene sequencing.[25] For subspeciation of MABSC, a multilocus sequence typing approach has recently been validated.[26] Each of these methods has significant strengths as well as disadvantages, and there is no consensus regarding the gold standard for NTM identification. However, recently published guidelines sponsored by the CF Foundation (CFF) and the European CF Society (ECFS) recommend that all NTM isolates from individuals with CF should undergo molecular identification.[20] All MABSC isolates from individuals with CF should be identified to the subspecies level, and other NTM identified to the species level, except for *M. avium, M. intracellulare,* and *M. chimaera,* where identification can be limited to MAC.[20]

# Epidemiology

## Prevalence

## General Population

Several problems compound the epidemiologic description of NTM infections in children.[19] NTM infection is rarely a cause of death, with an overall mortality rate of 2.3 deaths per 1,000,000 person-years attributed to NTM in the United States.[27] In individuals age 24 years and younger, age-adjusted mortality rates range from 0.04 to 0.12 per 1,000,000 in the absence of an HIV diagnosis, and are even lower in the presence of an HIV diagnosis.[27] Smaller laboratories that isolate NTM often do not refer isolates to reference laboratories for identification and drug-susceptibility testing, so statistics from reference laboratories grossly underestimate the incidence of NTM disease. Finally, as opportunistic environmental bacteria with relatively low pathogenic potential, isolation of an NTM from a clinical specimen is rarely sufficient for the diagnosis of disease. Distinguishing among environmental contaminants, transient recovery of the bacteria, colonizers, and truly pathogenic organisms requires clinical correlation that is not available based simply on laboratory reports. A recent study of NTM disease prevalence in the United States estimated 27.9 cases per 100,000 population,[28] based primarily on Medicare beneficiary data. These authors estimated 31% of cases were less than 65 years old, but the actual number of pediatric cases is unknown.[28] Substantial differences in susceptibility to NTM pulmonary disease appear linked to race and ethnicity.[1] Within the Hawaiian Islands, which has a rate of NTM pulmonary disease four times greater than the national average in the United States,[2] prevalence was highest among Japanese, Chinese, and Vietnamese patients (>300/100,000 persons) and lowest among Native Hawaiians and Other Pacific Islanders (50/100,000).[1]

## Cystic Fibrosis

The best estimates for the prevalence of positive NTM cultures comes from CF populations, where the rate of infection has been studied in prospective and retrospective clinical trials, as well as in extensive longitudinal data collection through national registries. In the largest studies, the overall prevalence is 6%–13%.[29–35] Since 2010, the US CF Patient Care Registry has tracked the presence of positive NTM culture, and over a 4-year span (2011–2015), 19% of patients who were cultured had one or more species isolated.[10] There is widespread agreement that the prevalence of NTM is increasing in the CF population[10–12]; however, it is often difficult to compare reports from single centers or even national surveys because of widely differing methods of ascertainment, regional environmental differences, culture methods, and the definitions of colonization, infection, and disease. CF features underlying progressive pulmonary disease and chronic airway infections with highly pathogenic bacteria such *P. aeruginosa* and *Staphylococcus aureus*.[36] In this setting, it is challenging to assess the role of an NTM infection in an individual patient. While the isolation of an NTM from a CF patient's sputum may be associated with a worsening clinical and radiographic course, in the majority of patients a positive NTM culture may be a transient occurrence or not associated with measurable acceleration of disease.[15]

In CF patients in whom NTM disease is diagnosed, there are apparent differences between those infected with MABSC and MAC. Patients infected with MABSC are often younger, and may include children, with relatively more severe lung disease.[12,37] Those infected with MAC are often older and more frequently heterozygous for residual function cystic fibrosis transmembrane conductance regulator (CFTR) mutations, resulting in a less severe phenotype, which may not be diagnosed until adulthood.[30,37,38] There are, of course, many exceptions to this general observation, and children with CF can develop NTM disease from either MAC or MABSC. Disease from MABSC is the more feared infection due to a more difficult course of treatment, a poorer response to antibiotic therapy, an often more severe clinical course, and frequent exclusion from lung transplant in the setting of failure to eradicate the bacteria.[12,20,39]

## Human Immunodeficiency Virus Infection/Acquired Immune Deficiency Syndrome

Clinical disease due to NTM is common in adults and children with AIDS. MAC accounts for most cases, followed in incidence by *M. kansasii*.[40] The predominant risk factor appears to be a CD4 cell number below 50 cells/mm$^3$, and can occur as either disseminated or localized disease.[41] Other NTM that have been described as disease-causing in HIV/AIDS include *Mycobacterium xenopi,*[42] *Mycobacterium haemophilum,*[17] *Mycobacterium fortuitum* or *Mycobacterium chelonae,*[43] *Mycobacterium genavense,*[44] *Mycobacterium simiae,*[45] and *Mycobacterium szulgai.*[46] A high clinical suspicion is needed for either unexplained lymphadenitis, cutaneous or systemic presentations in patients with CD4 cell < 50 cells/mm$^3$.

## Mendelian Susceptibility to Mycobacterial Disease and Other Immunocompromised Conditions

Mendelian susceptibility to mycobacterial diseases (MSMD, MIM #209950) is caused by genetic defects in the mononuclear phagocyte/T helper cell type 1 (Th1) arm of host defense.[14] Patients with MSMD have increased susceptibility to systemic NTM infections, even including the Bacillus Calmette-Guérin vaccine strain. All the MSMD conditions feature defects in the interferon gamma (IFN-gamma)-interleukin-12 pathway and/or supporting accessory pathways (Table 30.1). In about half of patients with MSMD, the genetic etiology has yet to be identified.[47]

### Table 30.1

**Diseases Associated With Nontuberculous Mycobacteria Infection**

| | |
|---|---|
| Mendelian susceptibility to mycobacterial diseases (MSMD) | Autosomal recessive complete interferon-gamma receptor deficiencies[140]<br>Autosomal dominant partial interferon-gamma receptor deficiencies[140,141]<br>IFN-gamma-R1 *(IFNGR1)*[141] or IFN-gamma-R2 *(IFNGR2)*[142]<br>Autosomal recessive partial IFN-gamma receptor deficiencies[143,144]<br>IL-12 receptor beta1 *(IL12RB1)* deficiency[14,145,146]<br>IL-12 p40 *(IL12B)* deficiency[147]<br>Autosomal recessive signal transducer and activator of transcription 1 *(STAT1)* deficiency[14,148,149]<br>Autosomal dominant STAT1 *(STAT1)* deficiency[150]<br>Tyrosine kinase 2 (TYK2) deficiency[151]<br>Autosomal recessive IFN regulatory factor 8 *(IRF8)* deficiency[152–154]<br>Autosomal dominant IFN regulatory factor 8 *(IRF8)* deficiency[152–154]<br>GATA2 *(GATA2)* deficiency (monoMAC syndrome)[155,156]<br>Autosomal recessive IFN-stimulated gene 15 *(ISG15)* deficiency[84]<br>RAR-related Orphan Receptor C (RORC) dysfunction[157] |

| Structural lung disease[48] | Cystic fibrosis (CF)[36]<br>Alpha-1 antitrypsin deficiency[173]<br>Non-CF bronchiectasis[174]<br>Pneumoconiosis[175]<br>Pulmonary alveolar proteinosis[176]<br>Chronic obstructive pulmonary disease[177] |

*IFN,* Interferon; IL, interleukin; *TNFα,* tumor necrosis factor alpha.

Disseminated disease with pulmonary involvement caused by NTM has been described in patients with a variety of other rare immunodeficiency states, as well as malignancies including leukemia and lymphoma. Inherited and acquired defects in the host immune response include auto-antibodies to IFN-gamma, CD4 lymphopenia due to HIV or other causes, and use of tumor necrosis factor-alpha inhibitors, particularly infliximab and adalimumab. A wide variety of biologic and synthetic small molecules target aspects of host defense against NTM, and carry high theoretical risks for the infection.[48] NTM disease also has been reported in adults and children after organ transplantation.

## Environmental Risk Factors and Spatial Clusters

Distribution of NTM in the general population and in vulnerable populations varies dramatically by regions,[2,30,31] reflecting, in part, the environmental origin of the bacteria.[50] In the United States, the greatest number of estimated cases per 100,000 populations was 164.6 in Hawaii, followed by Florida (53.6), Mississippi (52), and Arizona (48.9). The states with the lowest rates were largely clustered in the upper Midwest, including Montana (5.4), South Dakota (6.5), North Dakota (7.4), and Minnesota (9.3).[28] These differences likely reflect a combination of host and environmental risk factors within these regions. A greater understanding of environmental risk factors and spatial clusters of NTM infection has come from the analysis of Medicare and Medicaid data, combined with population and socioeconomic data from the US Census Bureau, and environmental and climatic data from the US Census Bureau, US Forest Service, and the US Geological Survey.[51] Counties in high-risk areas were significantly larger, had greater population densities, and higher education and income levels than low-risk counties. High-risk counties also had higher mean daily potential evapotranspiration levels and percentages covered by surface water, and were more likely to have greater copper and sodium levels in the soil, with lower manganese levels.[51] Similar conclusions have been found from combining CF Patient Registry data with climatic databases, where higher saturated vapor pressure increased the risk for NTM (odds ratio = 1.06; 95% confidence interval = 1.02–1.10).[52]

The species of NTM causing infection also demonstrates significant regional differences. Nearly all surveys from European countries have established that MABSC is the most frequent NTM isolated from CF patients in those regions.[12,30,53] In contrast, reports from the United States have consistently shown MAC to be the predominant NTM infection.[15,31,52] In somewhat isolated regions, other NTM may be highly represented. For example, *M. simiae* is reported as the most frequent cause of NTM pulmonary disease in CF patients on the Island of Gran Canaria[54] and is also common in Israel.[11] Even within the US CF population, dramatic state-by-state differences in prevalence of various NTM species have been reported. When CF Patient Registry data were analyzed, 60% of positive cultures nationwide were identified as MAC, ranging by state from 29% in Louisiana to 100% in Nebraska and Delaware.[52]

## Acquisition and Potential for Transmission

Nearly all acquisition of NTM by children occurs from environmental sources, including soil, water, dust, and aerosols.[50]

MAC species are found frequently in animals, particularly birds and swine, which may be important natural reservoirs for the organisms. However, there is little evidence to suggest that animal-to-human transmission is a major factor in human infection.

The number of reported clusters of health-care-associated disease caused by various species of NTM is growing. Most common are outbreaks by the rapid growers. Both clusters and sporadic NTM infections have been associated with a variety of surgical procedures, including sternal wound infections after open heart surgery, augmentation mammoplasty, corneal surgery, implantation of pressure equalizing tubes in the tympanic membranes, and insertion of central venous catheters.[55–63] A number of outbreaks or pseudo-outbreaks of respiratory tract colonization caused by various NTM species have been associated with contaminated ice machines, showers, potable water supplies, laboratory supplies, topical anesthetics, and tap water in hospitals.[64–66] Contamination of endoscopes, bronchoscopes or bronchoscopy supplies has been implicated in some of these outbreaks.[61,67]

There is also growing concern over the potential for human-to-human transmission. Until recently, this was believed to never occur,[19] but with improved surveillance and increased availability of whole genome sequencing, several outbreaks have been reported. Well-described clusters of highly similar strains of *M. massiliense* have been reported in CF centers in Seattle, Washington, and Papworth, United Kingdom, in patients who were seen within the same clinic or hospital ward over a relatively short interval of time.[68,69] Mechanisms of NTM transmission are not well understood, but in well-defined localized outbreaks, it seems that shared exposure of a contaminated clinical space is a more plausible mechanism of pathogen spread than direct patient-to-patient transmission.[68] Strict infection control procedures following the Seattle outbreak have been associated with a cessation of any additional cases.[70] More recently, a much larger study found highly similar clusters of both *M. massiliense* and *M. abscessus* represented in collections of clinical isolates from United States, European, and Australian CF centers, indicating transcontinental dissemination of these clades.[71] Unlike the previous outbreaks in Seattle or

Papworth, there was no clear epidemiologic link between patients or physicians traveling between these different centers worldwide. In many cases, shared strains have been associated with increased virulence, antibiotic resistance and/or worse outcomes.[68,69,71] There is ongoing debate about whether these findings represent global transmission of strains of MABSC between CF centers through yet-to-be-defined mechanisms, or dominant environmental strains that are present worldwide with extremely low genetic diversity, or a combination of both.[72]

## Apparent Increase in Nontuberculous Mycobacteria Vulnerable Populations and in the Modern Environment

The incidence of detecting various NTM organisms in surveys of the general population, as well as individuals with CF appears to be increasing.[1–12] The underlying cause of this apparent increase is almost certainly multifactorial and interconnected. Within the CF population, impressive gains in projected lifespan puts greater numbers of patients at risk for NTM. Infection with MAC, in particular, is clearly age-related[37] and associated with long-term survivors with a milder phenotype.[37,38] Certainly, improved culture techniques and greater awareness among providers to consider NTM infection has contributed to the increase in positive NTM cultures.[20,22] There is also considerable debate as to whether various medications and CF treatment strategies directly place patients at increased risk. Some reports have implicated systemic steroids, high-dose ibuprofen, the higher use of antipseudomonal antibiotics, and chronic azithromycin therapy as being associated with higher prevalence of NTM-positive cultures and/or disease. However, for each of these medications, the opposite findings have also been reported.[36,73]

To a certain extent, these same considerations may apply to individuals within the general population with less well-defined risks for NTM. Certainly, humanity has never before included as many individuals with various forms of immunosuppression, ranging from HIV/AIDS to malignancies, and to the use of steroid and immunomodulatory drugs.[74] Presumably, physicians caring for these individuals are increasingly aware of the potential risks for NTM infection, and are practicing appropriate culture surveillance. Certainly, nosocomial risks for acquisition of NTM are well described, particularly in the setting of surgery or other invasive procedures,[56–67,75,76] and this may extend to patient-to-patient transmission in some settings, as discussed above. Finally, there is growing evidence that many features of the modern environment may favor NTM survival and a higher potential burden of exposure. These factors may include high density urban populations,[30,51] plumbing and water supply systems,[77,78] the use of showers,[79] and lower temperatures of hot water heaters in homes and hospitals.[60,77] Climate change has also been implicated in the apparent increase in NTM, as higher temperatures are linked to increased evaporation of water, and the increase in natural disasters, which have been correlated with local outbreaks of NTM.[9] While risks related to nosocomial acquisition can be addressed, most of the other factors identified as relating to increased prevalence of NTM in the modern environment, and in vulnerable patient populations, are expected to increase for the foreseeable future, and to result in a continued increase of infections by NTM.

## Clinical Manifestations of Nontuberculous Mycobacteria Pulmonary Disease

Clinical and radiographic manifestations of NTM pulmonary disease are described in Table 30.2. Children can present with any combination of clinical signs and symptoms, though most patients experience chronic cough and sputum production that do not improve with the antibiotic treatment that is used for more typical lung pathogens, or with the use of corticosteroids.[19,80] Radiographic signs include presence of single or multiple pulmonary nodules, tree-in-bud opacities, large areas of consolidation, or bronchiectasis (Fig. 30.1).[81] Additionally, cavitation is an important finding representing more significant tissue destruction. Importantly, in patients with CF, there is significant overlap of both clinical and radiographic NTM manifestations with underlying pulmonary disease and chronic airway infection due to more common CF pathogens such as *P. aeruginosa or S. aureus,* as well as symptoms related to CF comorbidities, including CF-related diabetes and allergic bronchopulmonary aspergillosis (ABPA). In patients with CF, one should suspect NTM infection in those with constitutional or respiratory symptoms above baseline, unexplained increased decline in lung function, and progressive radiographic disease that are not responsive to typical CF therapies and antibiotics.[15,20,82,83]

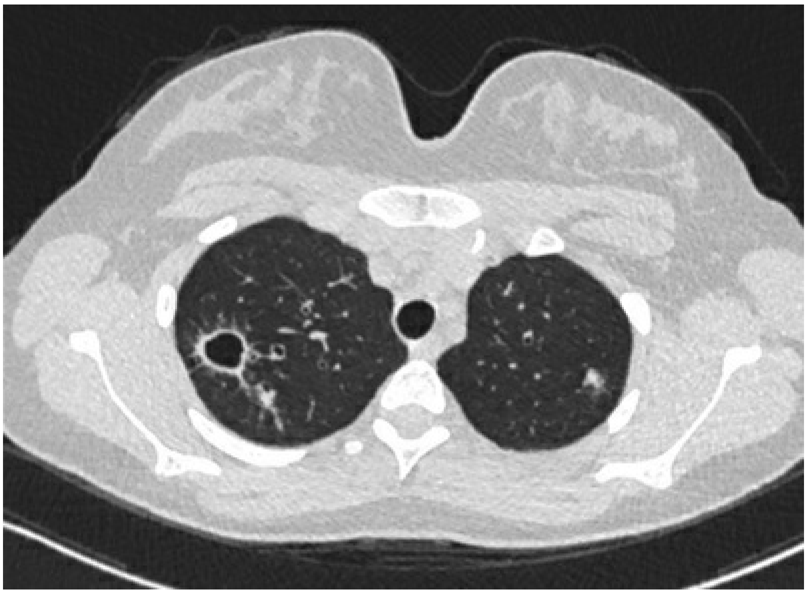

**FIG. 30.1** Radiographic findings of nontuberculous mycobacteria pulmonary disease in a patient with cystic fibrosis (CF). The patient is a 16-year-old with CF with multiple positive cultures for *Mycobacterium abscessus,* a decline in pulmonary function, and the presence of clinical syndrome symptoms that persisted despite several courses of prolonged intravenous, oral, and inhaled antibiotics. This computed tomography image shows bilateral bronchiectasis and airway wall thickening, bilateral pulmonary nodules, and the presence of a new 2.1 cm cavitary lesion in the right upper lobe in the region of a previously identified small pulmonary nodule.

# Diagnosis of Nontuberculous Mycobacteria Pulmonary Disease

## Clinical Criteria

To make the diagnosis of NTM pulmonary disease in a child, a patient must meet both microbiologic and clinical criteria with appropriate exclusion of other diagnoses (Box 30.1).[19] Clinical and radiographic findings are described above. In patients with CF, it is essential to first treat underlying typical CF pathogens, maximize airway clearance, and adequately assess for and treat CF-related comorbidities to ensure the clinical syndrome is not a consequence of underlying CF alone, prior to diagnosing NTM pulmonary disease.[20]

**Box 30.1**

## American Thoracic Society and Infectious Disease Society of America Clinical and Microbiologic Criteria for Diagnosis of Nontuberculous Mycobacteria Pulmonary Disease

### Clinical Criteria (Both Required):

1. Pulmonary symptoms, nodular or cavitary opacities on chest radiograph, or a high-resolution computed tomography scan that shows multifocal bronchiectasis with multiple small nodules.
2. Appropriate exclusion of other diagnoses.

### Microbiologic Criteria (One of the Following Required):

1. Positive culture results from at least two separate expectorated sputum samples.
2. Positive culture results from at least one bronchial wash or lavage.
3. Transbronchial or other lung biopsy with mycobacterial histopathologic features (granulomatous inflammation or AFB) and positive culture for NTM or biopsy showing mycobacterial histopathologic features (granulomatous inflammation or AFB) and one or more sputum or bronchial washings that are culture positive for NTM.

*AFB,* Acid-fast bacilli; *NTM,* nontuberculous mycobacteria.

## Microbiologic Criteria

In contrast to *M. tuberculosis,* a single positive culture for NTM does not necessarily constitute a disease that requires treatment in patients both with and without CF. Individuals should have two or more positive sputum cultures for the same NTM species. An exception is that a positive culture from a single bronchial wash or lavage, or from transbronchial or other lung tissue biopsy, can be sufficient if NTM is highly suspected. Expert consultation should be obtained when NTM that are either infrequently encountered or that usually represent environmental contamination are recovered from culture.[19] Patients who are suspected of having NTM lung disease, but who do not meet the diagnostic criteria, should be followed closely with increased surveillance of sputum acid-fast bacilli (AFB) smears and cultures until the diagnosis is firmly established or excluded. Importantly, making the diagnosis of NTM pulmonary disease does not necessarily require initiation of treatment. Due to the burden of treatment, risk of emergence of resistance with partial treatment, and potential treatment-related side effects, the risks and benefits of therapy for the individual patient must be considered and discussed prior to initiating therapy.[19,80]

## Extrapulmonary Nontuberculous Mycobacteria Disease

Extrapulmonary NTM disease in children most commonly occurs as lymphadenitis, typically in the cervical lymph nodes.[84] Localized disease can happen in both immunocompetent and immunocompromised children and presents with fever, leukocytosis, and focal inflammation in a lymph node (cervical, intraabdominal, or mediastinal). The diagnosis is confirmed by AFB culture from an aspirate of the node.[85] Less common are skin and soft-tissue infections due to NTM. A high level of suspicion when evaluating a nonhealing wound should prompt collection of AFB cultures. Disseminated NTM disease is uncommon in children, most typically occurring in an immunocompromised child. Disseminated MAC presents as fever, night sweats, abdominal pain, diarrhea, and weight loss, with the diagnosis confirmed through isolation of MAC from blood cultures. *M. kansasii* can present similarly with features that resemble *M. tuberculosis.*[86] Notably, in extrapulmonary or disseminated disease, a single culture from a wound or blood is sufficient for diagnosis, and treatment should be initiated.

## Management and Treatment

Treatment of NTM disease depends on the location and extent of disease, the species causing infection, and the drug resistance pattern of the organism.[19] Precise speciation is critical for directing antimicrobial therapy as treatment outcomes vary depending on the causative species. Unfortunately, drug susceptibility test results do not correlate well with treatment outcomes, except for the macrolides and amikacin in pulmonary MAC,[19,87] rifampin in pulmonary *M. kansasii,*[19] and macrolides in MABSC.[88,89]

The drugs most commonly used to treat NTM infections are listed in Table 30.3. Multiple-drug therapy is used for all mycobacterial infections because of the propensity of these organisms to develop resistance.[19] The treatment regimens for children with NTM disease are based on either limited clinical trials in adults or anecdotal evidence from small series or case reports. Standard treatment regimens typically include at least three drugs directed against the specific NTM pathogen, in the oral, inhaled, and/or intravenous forms.[19] Empirical therapy is not advised in most settings as treatment varies significantly between species. However, in settings where tuberculosis is endemic or clinically suspected, empirical therapy for tuberculosis is recommended pending the results of diagnostic studies.

**Commonly Used Drugs for Nontuberculous Mycobacterial**

## Infections With Adverse Reactions and Suggested Monitoring

| Drug | Route of Administration | Pediatric Dosage | Adverse Reactions | Suggested Monitoring |
|---|---|---|---|---|
| Amikacin | Intravenous | Children: 15–30 mg/kg per dose once daily<br>Adolescents:10–15 mg/kg per dose once daily (maximum dose 1500 mg daily) | Nephrotoxicity, auditory-vestibular toxicity | Creatinin<br>Serum amikacin levels<br>Hearing exams<br>Clinical symptom |
| Amikacin | Nebulized | 250–500 mg/dose once or twice daily | Auditory-vestibular toxicity | Hearing exams<br>Clinical symptom |
| Azithromycin | Oral | Children: 10–12 mg/kg per dose once daily (maximum dose 500 mg daily)<br>Adolescents: 250–500 mg daily | Nausea, vomiting, diarrhea, auditory-vestibular toxicity, prolonged QT | Clinical symptom<br>Hearing exams<br>EKG |
| Cefoxitin | Intravenous | 50 mg/kg per dose three times daily (maximum dose 12 g/day) | Fever, rash, cytopenias, eosinophilia | Complet blood count<br>Clinical symptom |
| Clarithromycin | Oral | 7.5 mg/kg per dose twice daily (maximum dose 500 mg daily) | Hepatitis, taste disturbance, inhibits metabolism of rifabutin | Clinical symptoms |
| Clofazimine | Oral | 1–2 mg/kg per dose once daily (maximum dose 100 mg daily) | Discoloration of skin, enteropathy, nausea, vomiting, prolonged QT | Liver function tests[120]<br>Clinical symptom<br>EKG[120] |
| Ethambutol | Oral | 15 mg/kg per dose once daily | Optic neuritis, peripheral neuropathy | Liver function tests<br>Eye exam<br>Clinical symptom |
| Imipenem | Intravenous | 15–20 mg/kg per dose twice daily (maximum 1000 mg per dose) | Nausea, vomiting, diarrhea, hepatitis, fever, rash | Liver function tests<br>Complet blood count<br>Clinical symptom |
| Isoniazid | Oral | 5 mg/kg per dose | Hepatitis, peripheral | Liver |

| | | | | |
|---|---|---|---|---|
| | | once daily | neuropathy | function tests<br>Clinical symptom |
| Linezolid | Oral, intravenous | <12 years: 10 mg/kg per dose three times daily<br>≥12 years: 10 mg/kg per dose once or twice daily (maximum 600 mg per dose) | Cytopenias, peripheral neuropathy, optic neuritis | Complete blood count<br>Eye exam<br>Clinical symptom |
| Minocycline | Oral | 2 mg/kg per dose once daily (maximum dose 200 mg) | Photosensitivity, nausea, vomiting, diarrhea, vertigo, tooth discoloration | Clinical symptoms |
| Moxifloxacin | Oral | 7.5–10 mg/kg per dose once daily (maximum dose 400 mg) | Nausea, vomiting, diarrhea, insomnia, agitation, anxiety, tendonitis, photosensitivity, prolonged QT | Clinical symptom<br>EKG |
| Rifabutin | Oral | 5–10 mg/kg per dose once daily (maximum dose 300 mg) | Cytopenias, orange discoloration of fluids, hepatitis, nausea, vomiting, diarrhea, hypersensitivity/flulike syndrome, increased metabolism of many drugs, uveitis | Liver function tests<br>Complete blood count<br>Clinical symptom |
| Rifampin | Oral | 10–20 mg/kg per dose once daily (maximum dose 600 mg) | Cytopenias, orange discoloration of fluids, hepatitis, nausea, vomiting, diarrhea, fever, chills, increased metabolism of many drugs, renal failure | Liver function tests<br>Complete blood count<br>Clinical symptom |
| Tigecycline | Intravenous | 8–11 years: 1.2 mg/kg per dose twice daily (maximum 50 mg per dose)<br>≥12 years: 50 mg once or twice daily | Nausea, vomiting, diarrhea, pancreatitis, hypoproteinemia, hepatitis | Liver function tests<br>Complete blood count<br>Clinical symptom |
| Trimethoprim-sulfamethoxazole | Oral | 10–20 mg/kg per dose twice daily | Nausea, vomiting, diarrhea, cytopenias, fever, rash | Complete blood count<br>Clinical symptom |

## Nontuberculous Mycobacteria Pulmonary Disease

There have been no clinical trials evaluating antibiotic treatment regimens for NTM lung disease in children, including those with CF. Treatment of NTM pulmonary disease should be based on American Thoracic Society and Infectious Disease Society of America (ATS/IDSA) guidelines[19] that were developed for the general population and CFF/ECFS guidelines developed specifically for treatment in the setting of CF.[20] While there is general agreement on which drug regimens should be used for the initial treatment of NTM infections, it is unclear what the optimal length of therapy is for children with NTM disease. The ATS/IDSA and CFF/ECFS recommend that patients be treated for 12 months beyond culture conversion, which is defined as three consecutive negative cultures with the time of conversion being the date of the first negative culture, and assuming there are no additional positive cultures during the 12 months.[19,20]

## Treatment OF *Mycobacterium avium* Complex Pulmonary Disease

Recommended regimens for the treatment of MAC lung disease in children are based entirely on the results of clinical trials in adults. Although there is only anecdotal information available for treatment of MAC pulmonary infections in children, the regimens used in adults seem to be effective in children. The most important determinants of treatment are the presence of macrolide resistance and cavitation. In macrolide-susceptible MAC disease, the initial treatment for noncavitary NTM lung disease due to MAC utilizes a three-drug regimen that includes a macrolide, rifamycin, and ethambutol.[19] Azithromycin is the macrolide usually chosen due to once daily dosing and reduced interactions with rifampin and the CYP3A enzyme system compared to clarithromycin.[19] Also, chronic azithromycin therapy has been shown to have benefits in people with CF due to immunomodulatory properties of the drug, in particular those patients with chronic *P. aeruginosa* infection.[90–92] Although azithromycin has recently been shown to reduce macrophage autophagy of *M. abscessus* in CF, suggesting that it has the potential to impair host defense independent of its antibiotic properties,[93] this potential detriment has not been identified in patients with NTM disease.

For patients without CF, with noncavitary disease, intermittent (i.e., three times weekly) oral therapy is recommended.[19] However, intermittent therapy is not recommended in patients with CF due to concerns about abnormal absorption of antimycobacterials and altered pharmacokinetics.[20] Instead, daily administration of the same mediations is preferred. In CF patients with MAC which is macrolide-resistant, or who are systemically ill or AFB smear positive, or who have evidence of a cavitary lesion on chest imaging, a 1- to 3-month course of intravenous daily amikacin may be added at the beginning of the treatment course along with the standard three oral antibiotics.[20]

Macrolide resistance is associated with a very poor prognosis. Risk factors for the development of macrolide-resistant MAC are macrolide monotherapy and prior macrolide therapy with inadequate companion drugs.[87] In non-CF patients, macrolide resistant MAC lung disease has been associated with sputum culture conversion rates as low as 5%–15%.[87,94] Patients with macrolide-resistant MAC should generally be managed in collaboration with an expert in the treatment of NTM disease.

## Treatment of *Mycobacterium kansasii* Pulmonary Disease

Because *M. kansasii* is rarely a contaminant, most patients with *M. kansasii* isolated from respiratory specimens should be considered to have the disease and should be treated accordingly.[19] While there have been no randomized, controlled trials of treatment for *M. kansasii,* treatment outcomes are usually good with rare treatment failures or relapses.[19] The current recommendation for treatment of pulmonary disease caused by *M. kansasii* is a regimen of isoniazid, rifampin, and ethambutol given daily for at least 12 months after the sputum culture has become negative.[19] Because the concentrations of drugs used in susceptibility testing were chosen for their usefulness with *M. tuberculosis* and not *M. kansasii,* some *M. kansasii* isolates may be reported to be resistant to isoniazid. However, these isolates are susceptible to slightly higher drug concentrations, and laboratory reports showing resistance to the lower concentrations have no clinical or therapeutic significance if a rifampin-containing regimen is being used.

Macrolides have excellent in vitro activity against *M. kansasii* and, in a murine model, clarithromycin was the most active single agent followed by rifampin and gatifloxacin.[95] Moreover, at least two clinical studies have reported excellent treatment outcomes when a macrolide is substituted for isoniazid.[96,97] Surgical resection is seldom required.

## Treatment of *Mycobacterium abscessus* Species Complex Pulmonary Disease

Treatment of pulmonary disease due to MABSC is complicated because of significant levels of in vitro resistance, the need for intravenous antibiotics, common adverse reactions, and generally poor treatment outcomes. As described previously, MABSC can be divided into three subspecies: *M. abscessus, M. massiliense,* and *M. bolletii.* Studies in CF[98] and non-CF[99–101] patients have clearly demonstrated that culture conversion is much more likely to occur in patients infected with *M. massiliense* compared with *M. abscessus.*[98] These differences are presumably related to the presence of a functional erm[41] gene in *M. abscessus* that results in inducible macrolide resistance, whereas in *M. massiliense* the gene is nonfunctional.[99]

The typical treatment regimen for MABSC involves an intensive phase followed by a continuation phase. The intensive phase should include 3–12 weeks of intravenous amikacin, plus one or more of the following agents: intravenous tigecycline, imipenem, or cefoxitin.[19,20] This regimen should also include oral drugs for which some degree of in vitro activity has been demonstrated. Whether a macrolide should be included in the regimen for *M. abscessus* or *M. bolletii* is debatable given the presence of an erm[41] gene in most strains. However, if this cannot be determined, or there is a potential benefit from the immunomodulatory activity of the macrolide, then the drug should be given. As noted previously, azithromycin is preferred over clarithromycin and there is some evidence to suggest it is associated with better treatment outcomes in non-CF adults.[101] The duration of the intensive phase will be determined by the severity of disease, the response to therapy, and the tolerability of the regimen.

After intravenous therapy, patients typically continue a combination of oral and inhaled treatments with adjustments of therapy based on culture conversion as well as clinical and radiographic response. The continuation phase should include inhaled amikacin in conjunction with 2–3 of the following daily oral antibiotics: minocycline, moxifloxacin, linezolid, and clofazimine.[19,20] If macrolides are used, they should be continued throughout the continuation phase. Changes to the drug regime are common, due to drug intolerance, side-effects, and lack of efficacy. In some cases, patients must be treated with intermittent courses of intravenous antibiotics to control spread of the infection. These patients should generally be managed in collaboration with an expert in the treatment of NTM disease.

## Surgical Treatment Options

Resection lung surgery (pneumonectomy, lobectomy, or segmentectomy) is sometimes performed in adults with NTM lung disease to improve treatment outcomes, particularly infections caused by *M. abscessus.* An initial period of chemotherapy to contain the infection followed by resection surgery and a more prolonged course of chemotherapy leads to high rates of sputum culture conversion. In primarily non-CF patients with NTM lung disease, culture conversion rates after surgical resection have been reported to be 80%–100% with relapse rates of 0%–16%.[102–107] Among cohorts of non-CF patients with MABSC lung disease, surgical resection increased culture conversion rates by 25%–

30%.[89,108] In patients with CF, the disease is generally more diffuse and it is difficult to identify, with certainty, a focus of NTM infection in the setting of coinfection with typical CF pathogens, such as *P. aeruginosa* and *S. aureus*. Furthermore, CF patients with a history of NTM are at a very high risk of acquiring a second NTM in their lifetime.[15] For these reasons, surgical resection is rarely recommended.[20] As this surgery is difficult to perform, it is important that the thoracic surgeon has experience in performing the procedures.

## Nonpharmacologic Treatment Options

For patients with underlying bronchiectasis, nonpharmacologic therapies that target the clearance of airway mucus are essential. This is particularly important in patients with CF where the NTM treatment regimen should be part of a comprehensive CF care plan that includes effective airway clearance, nutrition management, and treatment of CF comorbidities, such as sinus disease and CF-related diabetes.[36] This care is most effectively delivered at a CF care center, which utilizes a multidisciplinary approach, providing access to a respiratory therapist, a dietitian, and a social worker, in addition to nurses and physicians experienced in CF care.

## Extrapulmonary Nontuberculous Mycobacteria Disease

In general, treatment of extrapulmonary and disseminated NTM disease follows the same principles used in pulmonary disease with the exception that surgical debridement/excision plays a more critical role in the treatment of lymphadenitis, skin, and soft tissue infections. Cervical lymphadenitis is the most common clinical presentation of NTM in children.[109–111] Treatment is generally divided into observation without intervention, surgical excision, and antimicrobial therapy (with or without surgery). Without intervention, most children who develop cervical adenitis will eventually resolve the infection; however, the time to resolution may be prolonged (6–12 months) and result in significant scarring.[110,111] Surgical excision can involve total excision, partial excision, or curettage. Factors in favor of complete surgical excision include a greater chance of isolating the organism, higher cure rates, faster healing times, less need for repeat surgery, and improved esthetic outcomes.[110–114] Antimicrobial agents may be indicated in some patients alone or in combination with surgery. In a randomized, controlled trial comparing surgical excision with antimicrobial therapy alone (clarithromycin and rifabutin), cure was reported in 90% versus 66%, respectively.[113] Temporary facial palsy occurred in 14% of those undergoing surgery but was permanent in only one patient.

Skin and soft tissue infections are the next most common form of extrapulmonary disease in children, and are often due to rapidly growing mycobacteria.[109] Treatment usually involves surgical debridement, abscess drainage, and foreign-body removal. Treatment is based on susceptibility testing of the specific isolate because susceptibility patterns vary greatly even within a species.[114] Successful treatment of disease due to *M. fortuitum* can be accomplished sometimes with chemotherapy alone, although this is seldom the case with *M. abscessus.*

## Monitoring of Drug Toxicity and Clinical Response

Routine monitoring of drug toxicity is required, and a plan for monitoring should be set in place at the initiation of treatment. Patients should be evaluated for evidence of hearing loss, visual loss, renal impairment, and liver function abnormalities.[19,20] Monitoring is particularly important for patients on intravenous aminoglycosides. Patients with CF are commonly treated with aminoglycosides for other lung pathogens; therefore, they are prone to auditory-vestibular toxicity and renal injury, making baseline and regular audiology evaluations and monitoring of renal function essential.[36] Even with oral agents, the potential for drug-related side effects and toxicity is considerable, including bone marrow suppression and hepatitis. Patients receiving ethambutol, rifabutin, or linezolid should have their vision monitored routinely and the drug should be discontinued immediately at the first sign of vision disturbance. Suggested monitoring guidelines are depicted in Table

30.3.

## Alternative Drugs

Several additional drugs have been used to treat NTM infections, including fluoroquinolones, clofazimine, inhaled amikacin, linezolid, and bedaquiline. The fluoroquinolones are widely available and have variable in vitro and in vivo activity against MAC and typically poor activity against *M. abscessus*.[115–119] However, in refractory disease, there may be an indication for their use.[119] Clofazimine has historically been used with success as an alternative agent for patients with MAC, and more recently for those with MABSC.[120,121] Clofazimine is generally well tolerated with 6%–14% of patients having to stop due to drug-related intolerance. Inhaled amikacin has been used for many years in patients intolerant to parenteral aminoglycosides, or as an adjuvant to oral therapy, but adverse effects may limit its use.[122–124] Linezolid is an oxalidinone with broad antimycobacterial activity that has been used to treat multidrug-resistant tuberculosis as well as NTM. However, efficacy remains unknown, and use of the drug has been limited by high rates of adverse reactions, including peripheral neuropathy, optic neuritis, and cytopenias.[125,126] Bedaquiline is a diarylquinoline approved for the treatment of multidrug-resistant tuberculosis in adults with broad in vitro antimycobacterial activity for MAC.[127] Based on early data, there may be future potential for using bedaquiline in the treatment of refractory MAC or MABSC.[128]

# Outcomes

Outcomes associated with NTM in children are not well reported in the literature,[129] though there is increasing evidence that NTM has the ability to affect clinical status and to accelerate the progression of lung disease, which causes an increased rate of decline in pulmonary function.[15,83] Additionally, older adults with NTM respiratory isolates have higher mortality compared to those without; however, there is lack of evidence of causality.[130,131] Importantly, there are also reports that have shown no clinical impact,[132] and other reported cohorts of patients with positive NTM cultures that are either transient or not associated with evidence of pulmonary disease.[15,32,81,133–135]

With various treatment regimens among patients with and without CF, clearance of sputum in patients with MAC pulmonary disease is reported to range from 45% to 75%, while MABSC culture conversion rates are lower, and are typically reported in the 40%–50% range.[15,108,136,137] *M. massiliense* subspecies clearance rates are higher than *M. abscessus,* and are thought to be secondary to a lack of inducible macrolide resistance,[99] and *M. kansasii* treatment is successful in about 90% of patients.[19] Relapse following treatment occurs in up to 35% for MAC[138] and 23% for MABSC.[108,137] Additionally, in patients with CF previously infected with NTM, the presence of a future, second NTM species is common, and is reported in up to 26% of patients at 5 years and 36% at 10 years following the first NTM species cultured.[15] With treatment, stabilization or improvement in clinical symptoms of NTM pulmonary disease, including cough, sputum production, and fatigue, as well as radiographic measures have been shown.[89,108,139] Longitudinal follow-up of cases of CF patients with NTM have also shown evidence of stabilization of pulmonary function.[15,136]

## Prevention

Little is known about the prevention of NTM infection in any group of individuals. Because these organisms are ubiquitous in nature, it is impossible to prevent exposure to them except under the most extreme circumstances. There has been no recommendation about the use of chemotherapy to prevent NTM infection in patients with or without CF. Until the risk factors for acquisition are better delineated, chemoprophylaxis will not be a part of the management of this disease.

# The Pulmonary Mycoses

*Aaron Samuel Miller MD, MSPH, Robert William Wilmott BSc, MB, BS, MD, FRCP (UK)*

## Introduction

There is a wide range of pathogens that causes pneumonia in children. Fungal pathogens account for only a small percentage of community-acquired and nosocomially acquired pneumonias. When fungal infections of the lungs do occur, they can be caused by either endemic or opportunistic fungi. The endemic mycoses are a diverse group of fungal organisms that share several characteristics, including the ability to show temperature dimorphism (i.e., mold in the environment, yeasts/spherules at body temperature), ability to cause disease in otherwise healthy humans, and the tendency to occupy specific geographical regions. Fungi that cause opportunistic infections are typically seen in children with compromised immune systems, altered microbiota, or those with disrupted integumentary barriers. In some cases, however, the fungi that cause opportunistic infections can occur in normal hosts.

Pulmonary mycoses in humans can occur after inhalation of fungal spores, reactivation of a latent infection, or via hematogenous dissemination. Immunocompromised children, as well as those from geographic regions where endemic fungal infections occur, are at highest risk. The diagnosis of pulmonary fungal infection can be difficult, as the signs and symptoms of disease can be nonspecific and noninvasive diagnostic tests often have a low sensitivity. For these reasons, the diagnosis of pulmonary mycoses is often made presumptively based on a combination of factors including the clinical setting, chest imaging, and negative bacterial or viral studies. The prognosis of pulmonary fungal infections depends on the clinical scenario, as most children with endemic fungal infections recover from their illness, while the prognosis for immunocompromised patients is more guarded. The highest morbidity and mortality is seen in patients with prolonged or irreversible immunosuppression.

## Antifungal Drugs

Antifungal drugs for systemic fungal infections have evolved significantly over the past 25 years. Amphotericin B deoxycholate was initially developed in the early 1950s and is part of the polyene class.[1] For many decades this was the primary antifungal used for invasive fungal infections. This class of antifungals binds to ergosterol in the fungal cell membrane, which results in cell death. Amphotericin B has activity against a wide range of fungal pathogens and is still considered the treatment of choice for various pathogens and clinical scenarios in children. It is absorbed poorly by the gastrointestinal tract and is solubilized with sodium deoxycholate for intravenous (IV) administration. Amphotericin B has dose-dependent renal toxicity and hypokalemia. In the mid-1990s, various lipid formulations were released, including amphotericin B lipid complex (ABLC; Abelcet) and a small, unilamellar vesicle formulation (L-AmB; Ambisome). These drug preparations have decreased toxicity compared with the deoxycholate formulation. In regard to the pulmonary mycoses mentioned in this chapter, most experts believe that a lipid formulation should be used over the deoxycholate formulation when available.[2] One exception may be in neonates, where limited retrospective data suggest that the deoxycholate formulation has improved efficacy.[3] Another possible exception involves the use of the deoxycholate formulation for fungal infections of the kidneys, as a study of a murine candidiasis model showed that the lipid preparations did not penetrate well into the renal parenchyma.[4] Efforts are being made to develop an effective oral formulation of amphotericin B by using polymeric nanoparticles to facilitate absorption across the gastrointestinal epithelium.[5]

The azole class of antifungal drugs acts by inhibiting the synthesis of ergosterol, which is the major sterol in fungal cell membranes. This drug class can be divided into the imidazoles (e.g., clotrimazole, miconazole, ketoconazole), and the triazoles (e.g., fluconazole, itraconazole, voriconazole, posaconazole). The imidazoles are primarily limited to topical use, given their hepatic toxicity and antiandrogen effects. The azole class is fungistatic against yeasts and fungicidal against molds. The development of the triazole fluconazole in 1981 was a major advance in the treatment of systemic antifungal infections, as it has excellent activity against *Cryptococcus neoformans* and many *Candida* spp. while also having good cerebral spinal fluid (CSF) penetration. Some of the disadvantages of fluconazole are that it has no activity against molds and has variable activity against certain *Candida* spp. (i.e., *Candida glabrata* and *Candida krusei*). Fluconazole was followed by the introduction of other important azoles, such as itraconazole in 1992 (activity against *Aspergillus* spp. and *Histoplasma capsulatum*), voriconazole in 2002 (expanded activity against fluconazole-resistant *Candida* spp. and *Aspergillus* spp.), and posaconazole in 2006. Posaconazole is notable for being the first available azole with activity against the agents that cause mucormycosis. In 2015, the US Food and Drug Administration (FDA) approved isavuconazole for adults with invasive aspergillosis (IA) or mucormycosis. Although no pharmacokinetic studies have been performed in children, this drug is promising for those patients with IA or mucormycosis who are not able to tolerate amphotericin B or posaconazole therapy.[6,7] Transaminase elevation and peripheral neuropathy are notable adverse reactions to the azole class. Voriconazole is known for its visual side effects (e.g., photophobia, altered color discrimination) and central neurologic toxicity, which can manifest as hallucinations. These adverse reactions are typically reversible upon discontinuation of the drug.

The echinocandins are the newest class of antifungal agents that work by inhibiting beta-1,3-D-glucan synthase, resulting in the destruction of the fungal cell wall. This enzyme is not present in mammalian cells, resulting in a drug class with a low side-effect profile. In contrast to the azole class of antifungals, the echinocandin class is fungicidal against yeasts and fungistatic against molds. These drugs include caspofungin (approved in 2001), micafungin (approved in 2004), and anidulafungin (approved in 2006). The echinocandins are poorly absorbed through the digestive tract and are therefore available only in IV formulations. The echinocandins are not ideal for fungal infections of the central nervous system (CNS), eye, or urinary tract owing to poor tissue penetration. The echinocandins can occasionally cause elevation of the aminotransferases.

Flucytosine (also known as 5-fluorocytosine, or 5-FC) is a fluorinated pyrimidine analogue. It has activity against *Candida* spp. and *C. neoformans*. Given that resistance develops quickly when used as monotherapy, flucytosine is typically used in combination with amphotericin B or an azole. Bone marrow suppression and gastrointestinal upset are the most notable adverse reactions to this drug.

As of 2017, there are 14 individual antifungal agents approved by the FDA, some of which have several formulations.[2] Up-to-date pediatric-specific dosing recommendations of the previously mentioned antifungal drugs can be found in many sources.[2,8] It should be noted that some of the newer antifungal agents have not been adequately tested in neonates in regard to efficacy, safety, and pharmacokinetics/pharmacodynamics. For these reasons, until new data are available, the drugs of choice for neonates with invasive fungal infections are amphotericin B deoxycholate, fluconazole, and micafungin.[9]

# Endemic Mycoses

## Histoplasmosis

### Epidemiology

Histoplasmosis is caused by the organism *Histoplasma capsulatum*. It is typically found in soil throughout the world and is endemic in the central United States (Ohio and Mississippi River valleys) (Fig.

31.1). This organism thrives in areas with a high concentration of bird or bat excrement in the soil. As a mold, *H. capsulatum* forms microconidia that can be aerosolized and inhaled by humans. The infection risk is highest when people are exposed to disturbed soil in endemic areas (e.g., construction, farming). Caves and abandoned buildings can also put people at risk of inhalation. Person-to-person transmission is not thought to occur. Skin test reactivity is common in hyperendemic areas, with as many of 80% of the population having a positive skin test by 18 years of age.[10]

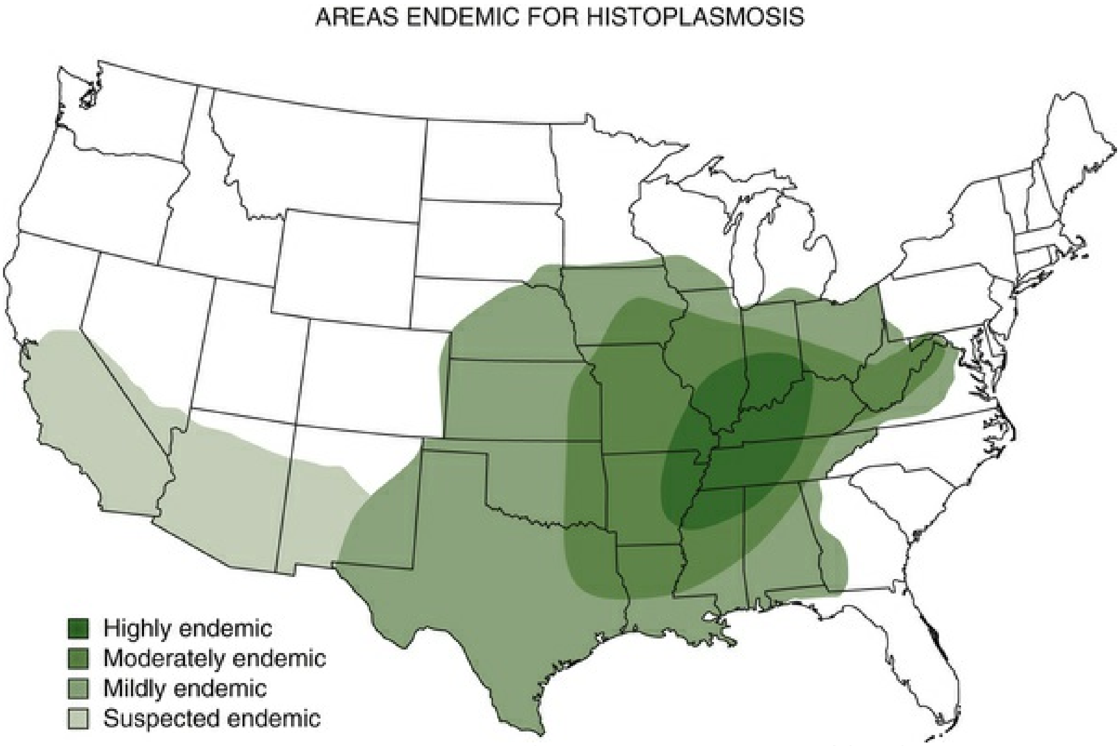

**FIG. 31.1** Areas endemic for histoplasmosis (CDC reference map).

## Etiology

*H. capsulatum* is a thermally dimorphic fungus that exists as a mold in the environment and as a yeast at human body temperature. At 25°C–30°C, the mold grows as a fluffy colony with spore-bearing aerial mycelia containing small oval microconidia and larger macroconidia. These infectious particles become airborne when soil is disrupted. At 37°C, the spores develop into a budding yeast form over a period of 7 days.

## Pathology/Pathogenesis

After inhalation, the microconidia germinate within the alveoli and distal bronchioles and transition to a yeastlike form. The yeast phase can enter and proliferate within macrophages.[11] Similar to tuberculosis, there is early transport to regional lymph nodes with formation of a primary complex. The normal host develops specific T-lymphocyte immunity with proinflammatory cytokine stimulation of the macrophages to kill the fungus. This results in an acute inflammatory reaction in the lungs. The histopathologic features of this process include granulomas and caseous necrosis. As these lesions heal, fibrosis and calcification can develop. Although uncommon in children, an exuberant fibrous response can cause destruction and obstruction of the lung parenchyma and other mediastinal structures.[12]

## Symptoms and Physical Findings

The majority of people exposed to *H. capsulatum* do not develop symptoms. Symptomatic infection occurs in fewer than 5% of infected individuals.[13] The risk of developing disease after exposure depends on inoculum size, degree of immunosuppression, strain-specific virulence factors, and preexisting immunity. The incubation period for the disease is typically 1–3 weeks after exposure. The clinical manifestations of histoplasmosis are classified according to physical location (pulmonary or disseminated), course of disease (acute, subacute or chronic), and whether the disease is a primary infection or due to reactivation of previous infection.[14]

### Pulmonary Histoplasmosis.

The most common symptomatic manifestation of histoplasmosis is acute pulmonary histoplasmosis. This begins as an acute inflammatory pneumonitis characterized by fever, nonproductive cough, and malaise. It is often a self-limited illness. For patients who develop more significant disease, the presenting signs and symptoms include persistent cough, nonpleuritic chest pain, wheezing, headache, fever, fatigue, myalgias, and arthralgias. These symptoms can last for 2–3 days or, in the subacute form, as long as 2–3 weeks. The acute form can also be accompanied by erythema nodosum, pericardial effusion, hypercalcemia, pleural effusion, or chylothorax. Unilateral wheezing is a classic pulmonary sign in patients with acute pulmonary histoplasmosis and is associated with bronchial compression. In the most severe cases of acute pulmonary histoplasmosis (typically due to a high inoculum), patients develop significant hypoxemia, diffuse reticulonodular infiltrates and acute respiratory distress syndrome (ARDS). Although acute disease is rare in children, adults with acute disease can go on to develop chronic cavitary pulmonary histoplasmosis. This process is associated with the "marching cavity," in which continuing necrosis leads to a progressively larger cavity that can consume the entire lobe.[11]

Acute pulmonary histoplasmosis can result in hilar or mediastinal lymphadenitis. In routine cases, a limited number of lymph nodes enlarge until the host's immune response is able to control the infection. In these cases, the lymph nodes eventually recede and calcify. In a smaller subset of patients, there is more significant enlargement of multiple hilar lymph nodes that become matted together and progress to granulomatous inflammation (mediastinal granuloma). This process can result in compression or obstruction of contiguous structures within the thorax, such as bronchi, trachea, pericardium, and pulmonary vasculature. Such compression can result in distal pneumonitis, pleural effusions, pulmonary infarction, pericarditis, and tracheoesophageal fistula formation. It is thought that the pericarditis and pleural effusions associated with acute pulmonary histoplasmosis are secondary to the inflammation of adjacent lymph nodes rather than direct fungal invasion.[14] The term *fibrosing mediastinitis* applies to excessive proliferation of invasive fibrous tissue within the mediastinum. It is thought to represent an abnormal immunologic host response rather than an active fungal infection. This leads to invasion of normal mediastinal structures such as the pulmonary vasculature, the superior vena cava, or the airways. Fibrosing mediastinitis occurs only rarely in children.[15]

### Disseminated Histoplasmosis.

Disseminated histoplasmosis can occur early in infection and is usually self-limited in the immunocompetent host. The term *progressive disseminated histoplasmosis* (PDH) applies to infections where there is overwhelming reticuloendothelial involvement; this is typically fatal if untreated. PDH can develop after acute infection or with recrudescence of previous histoplasmosis.[11] PDH is rare in children but can be seen in a variety of clinical situations. One form of PDH occurs in children with immunocompromising conditions such as hematologic malignancy, acquired immunodeficiency syndrome (AIDS), or those who have undergone a solid organ transplant (SOT). There is also an increased risk in those children who receive tumor necrosis factor (TNF) antagonists such as infliximab, adalimumab, and golimumab.[16,17] In these cases, the presenting symptom can be fever alone or respiratory distress.

Another rare but notable subset of patients with histoplasmosis is those with PDH of infancy. This form of PDH is subacute and has been described in otherwise healthy children less than 2 years of age. These infants typically present with fever, failure to thrive, hepatosplenomegaly, pancytopenia, pneumonitis, meningitis and disseminated intravascular coagulation. This clinical picture can initially be mistaken for leukemia. The expected cure rate is greater than 85% if the infection is recognized and treated promptly.[18]

## Imaging, Pulmonary Function Testing, Laboratory Findings

Patients with no known history of histoplasmosis can have incidental findings on their chest radiographs showing single or multiple calcified nodules in the lungs as well as mediastinal and hilar lymphadenopathy. Imaging of the chest of those with acute infection is variable and ranges from normal, to focal pneumonitis with mediastinal adenopathy, to extensive interstitial or reticulonodular infiltrates (Fig. 31.2A). Chest computed tomography (CT) can be used to better define pericardial involvement, along with bronchial or vascular compression (see Fig. 31.2B). Calcification of the liver or spleen can also be seen. Chronic pulmonary histoplasmosis with cavitary lesions is rarely seen in children and is more commonly seen in adults with preexisting obstructive pulmonary disease.[19]

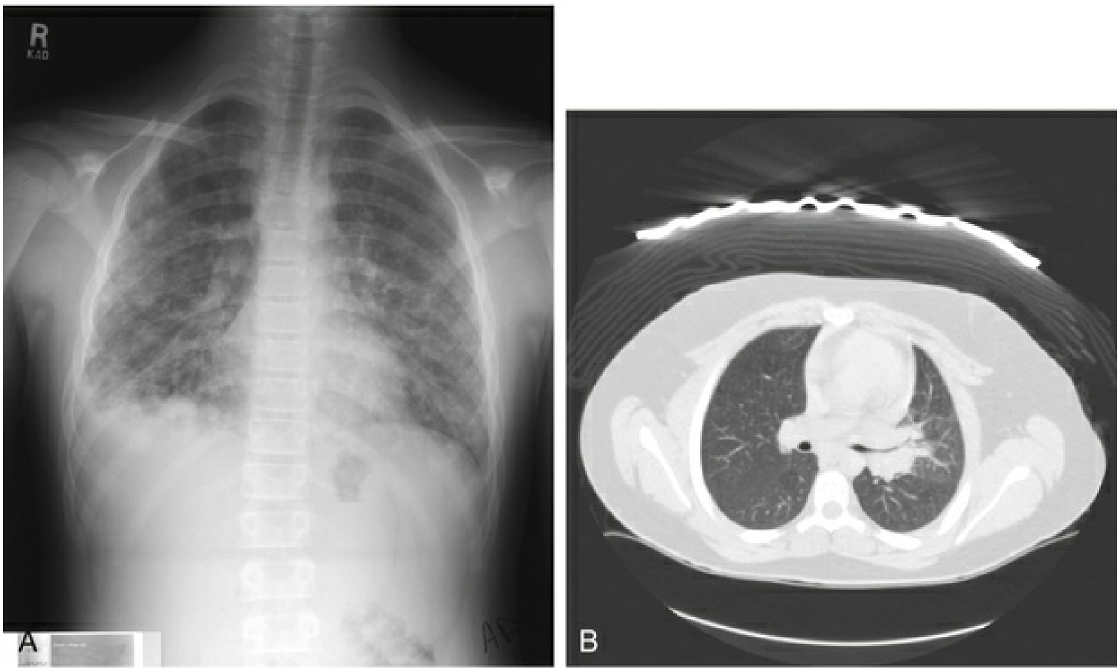

**FIG. 31.2** (A) Chest x-ray in acute histoplasmosis showing a diffuse interstitial process. (B) Cross-sectional computed tomography with narrowing of the right main stem bronchus attributable to hilar adenopathy in histoplasmosis.

## Diagnosis

The diagnosis of histoplasmosis can be challenging. Techniques used in this regard include histopathology, fungal culture, antigen detection, and serologic testing for *Histoplasma*-specific antibodies. Historically, an intradermal skin test was used, but this has fallen out of favor owing to a high rate of false-positive results in adults from endemic areas.[20]

*H. capsulatum* can be cultured from sputum, tissue specimens, and bone marrow on standard fungal culture media. Unfortunately the sensitivity is low in acute disease. Growth is seen in 1–6 weeks.[21] Histopathologic examination of biopsy specimens can allow for a rapid diagnosis. Specimens from lung, bronchoalveolar lavage (BAL) fluid, lymph nodes or bone marrow can show intracellular yeast forms using Gomori methenamine silver stains (Fig. 31.3E and F).[15,22]

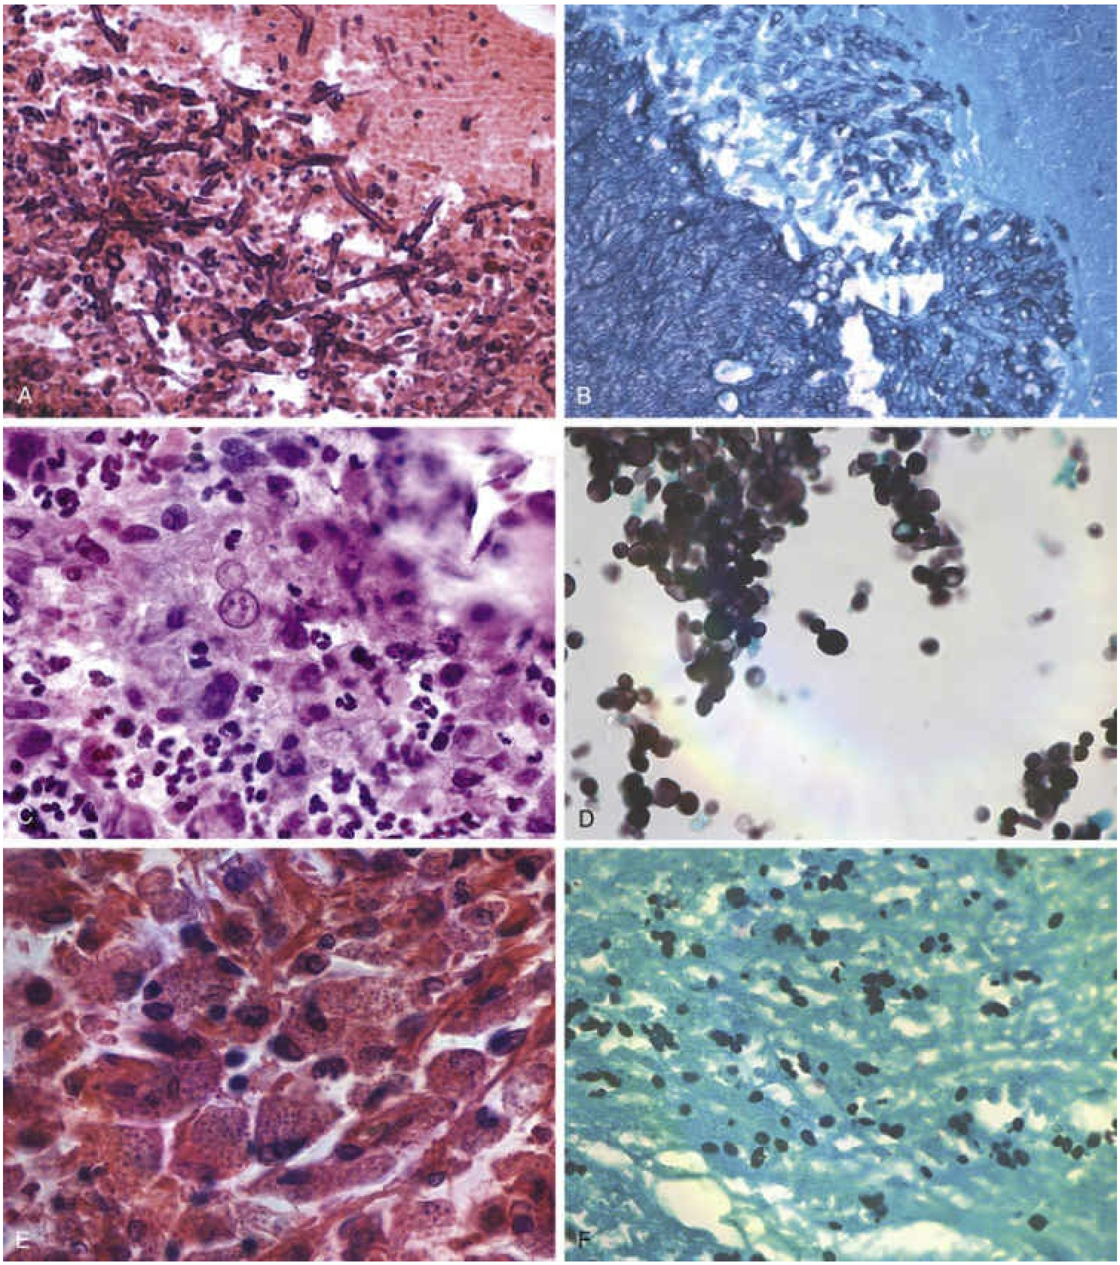

**FIG. 31.3** Panels showing the typical morphology of invasive aspergillosis (A and B), blastomycosis (C and D), and histoplasmosis (E and F). (A, C, and E) Hematoxylin and eosin. (B, D, and F) Gomori's methenamine silver stain.

Detection of *H. capsulatum* antigen from serum, urine, or BAL fluid can be done with a commercially available enzyme immunoassay (EIA). This test is most sensitive for severe pulmonary infections or progressive disseminated disease in adults but has a low sensitivity in primary disseminated disease in childhood or in the setting of immunosuppression. When positive, the antigen test can also be helpful in monitoring response to treatment and determining length of treatment. False-positive results are occasionally seen with other endemic fungal infections.[23]

The serologic diagnosis of histoplasmosis also has limitations. Acute pulmonary disease may be missed with this test, as serology does not become positive until 2–6 weeks after infection. Two different types of assays are available: an immunodiffusion test using antibodies to the M and H antigens of *H. capsulatum* and a complement fixation test that uses antigens from the yeast and mycelial forms. The complement fixation test is slightly more sensitive, while the immunodiffusion test has been found to be more specific. Complement fixation titers equal to or greater than 1 : 32 are highly suggestive of acute or recent infection. In the immunodiffusion test, results are reported as M or H bands. The H band is detectable in less than 20% of cases and is typically found to be positive in cases of disseminated infection or severe acute pulmonary histoplasmosis. Serologic tests are often negative in immunocompromised patients.[15]

## Differential Diagnosis

Pulmonary histoplasmosis with mediastinal lymph node involvement can mimic tuberculosis or lymphoma. Disseminated histoplasmosis of infancy can mimic leukemia or sepsis.

## Management and Treatment

Histoplasmosis in the normal host is usually a self-limited disease, and antifungal therapy is not required for mild to moderate disease in the immunocompetent host. Children who have persistent symptoms lasting longer than 4 weeks should receive a 6- to 12-week course of oral itraconazole. For severe or disseminated disease, the lipid formulation of amphotericin B is recommended for 1–2 weeks, followed by oral itraconazole for an additional 12 weeks (longer courses may be required for immunocompromised patients). Children being treated for PDH should not be transitioned to oral itraconazole until they have demonstrated clinical improvement and a decline in their serum *Histoplasma* antigen level. When using oral itraconazole, serum trough concentrations should be checked after 2 weeks of therapy to ensure that levels are greater than 1 μg/mL. Methylprednisolone should also be considered during the first 1–2 weeks of therapy in cases of severe respiratory disease. All children with chronic pulmonary histoplasmosis should be treated with a prolonged course of itraconazole (typically 1–2 years), and severe cases may require an initial course of amphotericin B.[15]

Children with the inflammatory mediastinal manifestations of histoplasmosis (e.g., mediastinal adenitis, pericarditis) may not require antifungal therapy. Mild to moderate cases of pericarditis or rheumatologic syndromes can be treated with nonsteroidal antiinflammatory drugs. In severe cases of mediastinal disease (e.g., adenitis leading to obstruction, severe pericarditis), corticosteroids can be used. In cases where corticosteroids are used, itraconazole should be used concurrently and continued for 6–12 weeks thereafter. General recommendations for the treatment of histoplasmosis in children and adults have been published by the Infectious Disease Society of America (IDSA).[15]

## Prevention

Children with impaired cellular immunity should be counseled about the risks of histoplasmosis if they are living in or visiting endemic areas. These patients should avoid activities that increase the risk of exposure, including cleaning household areas with significant dirt or dust (e.g., garages, basements, and barns), cutting firewood, gardening, or exposure to soil contaminated by bird or bat guano. If such activities are unavoidable, an appropriate mask should be worn.

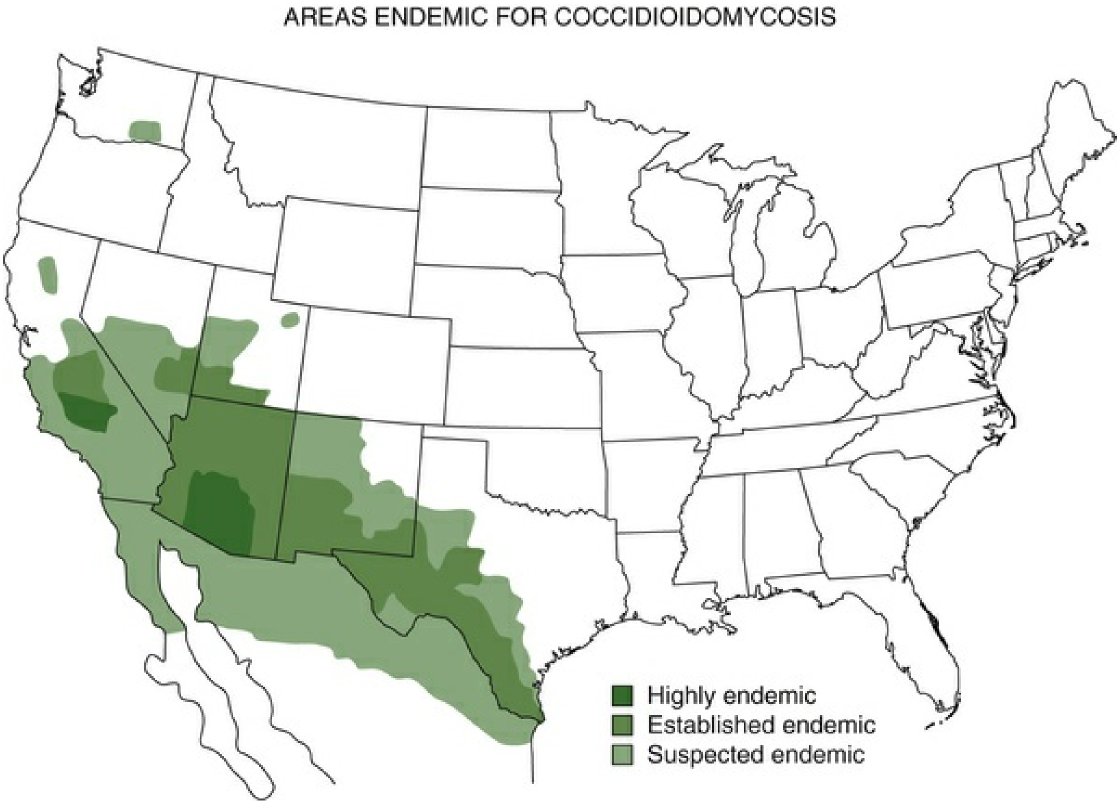
## Prognosis

The prognosis of children with histoplasmosis varies greatly based on the clinical scenario. In most children, the disease is unrecognized or self-limited. The cure rate for immunocompetent children with acute disease is high. PDH of infancy was considered uniformly fatal before effective antifungal agents were available, but survival rates are high with modern therapies.[18] Immunocompromised children with disseminated histoplasmosis have a more guarded prognosis.

# Coccidioidomycosis

## Epidemiology

Coccidioidomycosis, also known as San Joaquin Valley fever, is a systemic fungal infection caused by *Coccidioides immitis* and *Coccidioides posadasii*. Both organisms are found in geographic regions with low rainfall, high summer heat, and alkaline soil. Such geographic locations include the central valleys of California, Arizona, New Mexico, Nevada, and northern Mexico (Fig. 31.4). Children are at greatest risk of disease acquisition during the dry seasons of the year when there is increased exposure to dust. Person-to-person spread does not occur.



AREAS ENDEMIC FOR COCCIDIOIDOMYCOSIS
Highly endemic
Established endemic
Suspected endemic

**FIG. 31.4** Areas endemic for coccidioidomycosis.

## Etiology

*C. immitis* and *C. posadasii* grow as mycelia in the soil. The mycelia produce hyphae composed of barrel-shaped spores (arthroconidia), which are swept into the air when the soil is disrupted. These arthroconidia are inhaled into the alveolar spaces of the lungs and subsequently develop into round forms known as spherules, which contains multiple endospores. The spherules eventually rupture, releasing endospores into the adjacent tissues.[24]

## Pathology/Pathogenesis

The arthroconidia and spherules induce an immune response by neutrophils and macrophages, but phagocytosis is made difficult by the size of the fungal elements. Macrophages and dendritic cells exposed to the coccidioidal antigens stimulate the production of interferon gamma and other cytokines. This leads to further activation of phagosome-lysosome fusion and killing, followed by granulomatous inflammation of the affected area of the lung. Natural infection leads to lifelong immunity.[25]

## Clinical Features

Approximately 60% of humans infected with coccidioidomycosis have a subclinical infection. The remainder of infected individuals have symptomatic disease ranging from a self-limited influenza-like illness to more severe disease.[26] After inhalation of arthroconidia, there is an incubation period of 1–4 weeks. This is followed by cough, chest pain, fever, night sweats, arthralgias, and extreme fatigue. About one-third of infected patients will have clinically significant dyspnea. Acute infection can also be accompanied by a papular rash, erythema nodosum, or an erythema multiforme-like eruption. The combination of erythema nodosum, fever, and arthralgia has been described as "desert rheumatism." Other extrapulmonary manifestations are rare in children and include osteomyelitis and pustules that can ulcerate over time. The most severe manifestation of coccidioidomycosis is meningeal disease, which is seen in less than 1% of patients.[24]

Chronic forms of pulmonary coccidioidomycosis are seen but are uncommon in children. Patients with chronic disease may have had a mild primary infection that was not initially recognized as coccidioidomycosis. Chronic infection can result in cavitary lesions. Hemoptysis may often be the only symptom of a pulmonary cavity infected by *Coccidioides* spp. Risk factors for chronic pulmonary coccidioidomycosis include diabetes mellitus or an immunocompromising condition.

In one study of 41 children's hospitals in the United States from 2002 to 2007, Fisher et al. identified 199 children who required hospital admission for coccidioidomycosis. The authors found that 34% of the children had an underlying comorbid condition and 22% required at least one readmission for their disease during the study period.[27]

## Imaging, Pulmonary Function Testing, Laboratory Findings

Radiographic findings in pulmonary coccidioidomycosis are variable. Pulmonary nodules and thin-walled cavities can be seen on chest imaging, and some nodules will show calcification over time. Lobar, nodular, and patchy pulmonary infiltrates are all seen in acute disease, with or without hilar lymphadenopathy and pleural effusion. Cavitary lesions and bronchiectasis are all late features of pulmonary *Coccidioides* infection. In rare cases, rupture of a cavity may lead to severe disease with pyopneumothorax.[14]

## Diagnosis

Coccidioidomycosis may not be clinically recognized outside of endemic areas. Children with community-acquired pneumonia, especially with the dermatologic and rheumatologic symptoms already mentioned, should be considered for testing. The diagnosis of coccidioidomycosis is most often made with specific serologic tests utilizing EIA, immunodiffusion, or complement fixation–based tests. Antibody detection of IgG and IgM by EIA is the most sensitive assay and multiple commercially tests are available. Assays that utilize immunodiffusion or complement fixation are more specific. In general, approximately 50% of patients have IgM detected by 1 week of illness, and 90% have IgM detected by 3 weeks of illness. Unlike the case with other infections, IgG returns to normal levels after the infection resolves rather than remaining positive for life. Persistent high titers equal to or greater than 1 : 16 are seen with severe disease or disseminated infection.[28]

A second approach to the diagnosis of coccidioidomycosis is use of an EIA to detect *Coccidioides* antigens in urine, blood, or BAL fluid. This may prove useful in diagnosing coccidioidomycosis in patients who may not produce *Coccidioides*-specific antibodies. A small retrospective study of mostly immunocompromised patients found that *Coccidioides* antigenuria occurred in approximately 70% of patients with culture-proven infection, most of whom had severe disease. The assay proved to have a high negative predictive value except in patients who had infections with another endemic fungal infection.[29] Finally, coccidioidomycosis can be diagnosed by direct identification of the organism in its spherule form in biopsy tissue or BAL fluid. Isolation of *Coccidioides* from fungal culture is diagnostic. The organism grows rapidly on appropriate artificial media, with visible colonies of mold forming in 5–7 days. There is risk of infection to laboratory workers and the microbiology laboratory should be alerted prior to sending a sample if the disease is suspected.[24]

## Differential Diagnosis

Primary pulmonary coccidioidomycosis can resemble viral pneumonia, atypical pneumonia, bacterial pneumonia, tuberculosis, or other endemic fungal infections of the lungs.

## Management and Treatment

Treatment is not indicated for all patients. Asymptomatic patients who are found to have a pulmonary nodule from coccidioidomycosis and are otherwise healthy do not require treatment.[28] The benefit of treatment in immunocompetent patients with mild to moderate acute symptomatic infection is controversial. Some experts believe that antifungal therapy may decrease the length of illness or decrease the likelihood of severe infection. Suggested criteria to indicate severe disease include the need for hospitalization, weight loss of greater than 10%, persistent night sweats for greater than 3 weeks, pulmonary infiltrates involving both lungs or greater than half of one lung, prominent hilar lymphadenopathy, symptoms persisting over 2 months, inability to work or attend school, or a complement fixation titer of at least 1 : 16. Treatment should be strongly considered for those of African or Filipino descent, given higher rates of disseminated infection as compared with Caucasians. Although meningitis is uncommon in children with this infection, clinicians should have a low threshold for evaluating for the presence of CNS disease.

When treatment for coccidioidomycosis is indicated, an oral azole such is fluconazole is recommended for 3–6 months, depending on the clinical response. Regardless of whether antifungal therapy is started, patients with coccidioidomycosis should be followed every 1–3 months to document resolution of disease on chest x-ray (CXR) and monitored for new pulmonary or extrapulmonary complications.

Patients with active pulmonary coccidioidomycosis who are at increased risk for severe or disseminated infection should be treated with antifungal therapy. This includes patients with a history of human immunodeficiency virus (HIV) infection, hematopoietic stem cell transplant (HSCT), solid organ transplantation, prolonged exposure to corticosteroids or TNF inhibitors, or those who are pregnant. Treatment in these populations involves fluconazole or amphotericin B, depending on the extent of disease. Patients started on amphotericin B can be switched to oral fluconazole after clinical improvement. General recommendations for treatment of coccidioidomycosis in adults have been published by the IDSA and were last updated in 2016.[24]

## Prevention

Patients with impaired cellular immunity who live in or are visiting endemic areas should be counseled about the risks of coccidioidomycosis. This includes children with HIV, those on high-dose corticosteroids, those on anti-TNF therapies, those on antirejection medications after organ transplant, and women in their third trimester of pregnancy. Such patients should avoid activities that increase the risk of exposure, including environments where they would be exposed to large amount of dust from disrupted soil. If such activities are unavoidable, an appropriate mask should be worn. Preemptive therapy for coccidioidomycosis in special at-risk populations is recommended and is described in the IDSA guidelines.[24]

## Prognosis

The prognosis of children with coccidioidomycosis varies greatly based on the clinical scenario. The majority of patients have a self-limited disease process with complete recovery in 1–3 weeks. Mortality is low, even in children hospitalized for coccidioidomycosis. In the previously mentioned study by Fisher et al., the authors found that the overall in-house mortality for children admitted with coccidioidomycosis was 3 of 199 patients (1.5%).[27]

# Blastomycosis

## Epidemiology

Blastomycosis is another endemic fungal infection that has a geographic localization similar to that of histoplasmosis. This fungus grows best in warm, moist soil, and is endemic in the Ohio and Mississippi River valleys, in addition to the borders of the Great Lakes and the St. Lawrence River (Fig. 31.5). Blastomycosis is uncommon in children, with an estimated 3%–10% of all cases occurring in the pediatric population.[30]

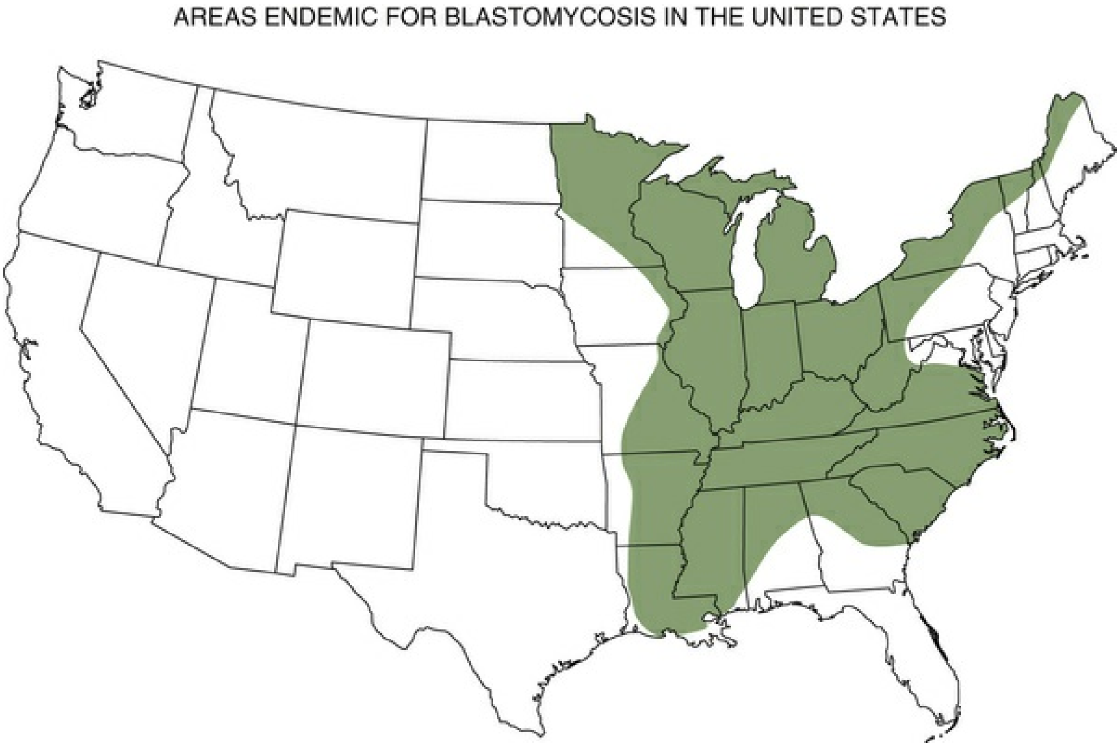


**FIG. 31.5** Areas endemic for blastomycosis.

## Etiology

*Blastomyces dermatitidis* is a thermally dimorphic fungus that exists in nature in a mycelial form and converts to a yeast at body temperature. The mycelial form is primarily found in the soil and consists of hyphae that produce conidia. These conidia are released into the air from the soil when it is disrupted and can subsequently be inhaled by humans.[31]

## Pathology/Pathogenesis

Blastomycosis can occur in immunocompetent and immunocompromised hosts. Population studies show that the infection is asymptomatic in 50% of children.[32] After *B. dermatitidis* conidia are inhaled by humans, the organism converts to pathogenic yeast. Alveolar macrophages and neutrophils are capable of phagocytizing and destroying conidia. The adaptive immune response is coordinated by T lymphocytes and is critical in activating a TNF-$\alpha$ response, which further enhances fungicidal activity. Conidia that evade this immune response can convert to the pathogenic yeast form in the lung and may subsequently disseminate.[30]

## Clinical Features (Symptoms/Physical Findings)

Blastomycosis is primarily a disease of the lungs. Children typically present with a prolonged illness consisting of fever, fatigue, cough, myalgias, and chest pain. In rare cases, a more severe ARDS presentation is seen. Between 38% and 50% of children with blastomycosis develop disseminated disease,[33,34] which can manifest as skin lesions (pustular, nodular, or ulcerative lesions), osteomyelitis, septic arthritis, or involvement of the genitourinary tract (prostatitis or epididymitis). Pulmonary blastomycosis can occasionally persist in the chronic form as chronic pulmonary blastomycosis. Symptoms may include productive cough, hemoptysis, and weight loss.[31]

## Imaging, Pulmonary Function Testing, Laboratory Findings

Chest imaging can show patchy pneumonitis, nodular lesions or lobar consolidation, which can occur with or without cavitation. Hilar and mediastinal lymphadenopathy is uncommon and should suggest an alternative diagnosis such as tuberculosis or histoplasmosis.[30]

## Diagnosis

The diagnosis of blastomycosis is based on visualization of the thick-walled, budding yeast cells on smears from sputum, tracheal aspirates, urine or tissue specimens (see Fig. 31.3C and D). In cases where the organism cannot be identified by examining sputum, BAL fluid can be cultured on brain/heart infusion or Sabouraud dextrose agar. Serologic testing by immunodiffusion or complement fixation assays lacks sensitivity.[32] A *Blastomyces* urine antigen test is commercially available, but a high degree of cross-reactivity is seen with other endemic mycoses. Real-time polymerase chain reaction (PCR) assays have been developed that can identify *B. dermatitidis* in various clinical specimens (e.g., pleural fluid, BAL fluid, sputum) with high sensitivity and specificity.[35]

## Differential Diagnosis

Acute pulmonary blastomycosis can mimic bacterial pneumonia, tuberculosis, sarcoidosis, or a malignant neoplasm. Chronic pulmonary blastomycosis can be mistaken for malignancy or tuberculosis. The skin lesions can be misdiagnosed as pyoderma gangrenosum.[30]

## Management and Treatment

Unlike acute pulmonary histoplasmosis or coccidioidomycosis, for which treatment is unnecessary in milder forms of disease, treatment of all forms of acute pulmonary blastomycosis is generally recommended.[31] The high rate of disseminated disease in children underscores this recommendation. For mild to moderate acute pulmonary disease, oral itraconazole is recommended for 6–12 months. For patients with moderate to severe pulmonary disease or those with disseminated extrapulmonary disease, amphotericin B (lipid or deoxycholate) should be given for 1–2 weeks or until improvement is noted. This should be followed by oral itraconazole for 6–12 months for pulmonary disease and at least 12 months for disseminated disease. Serum levels of itraconazole should be determined after the patient has received this agent for at least 2 weeks, to ensure adequate drug levels. It is recommended that serum itraconazole levels be greater than 1.0 mg/mL. General recommendations for the treatment of blastomycoses were last published in 2008 by the IDSA.[31]

### Prognosis

Overall mortality in adults with blastomycosis is reported to be 4%–6%, with an 18% mortality rate in those with CNS disease. Limited data are available in children, but mortality is thought to be lower in children than in adults due to the presence of less comorbidity.[30]

# Pulmonary Mycoses Primarily Seen in Hosts With Impaired Immunity

## Introduction

Children with altered immunity constitute a growing proportion of pediatric patients and the lungs are a frequent site of opportunistic fungal infections in this population.[36] Susceptibility to opportunistic fungi is increased in patients who undergo HSCT and receive cytotoxic chemotherapy, as these interventions result in decreased function and number of lymphocytes and phagocytes. Patients who receive such treatment often require indwelling catheters and invasive procedures, which further disrupt the normal barriers to immunity. Other risk factors for opportunistic fungal infections in children include those with AIDS, primary immunodeficiency syndromes, neonates with extreme prematurity and those with exposure to broad-spectrum antibiotics.

Diagnosis of pulmonary fungal infections in the immunocompromised child can be difficult, as the clinical presentation is often nonspecific. Likewise, radiographic patterns of disease in this population lack etiologic specificity, and microbiologic diagnosis is difficult without the use of invasive procedures to obtain specimens. For these reasons, clinicians must maintain a high index of suspicion for fungal infections in the immunocompromised child. Procedures such as bronchoscopy and lung biopsy must be carefully timed because the risks associated with an invasive procedure may become too high as the underlying disease progresses.

## Aspergillosis

The term *aspergillosis* can refer to disease related to allergy, airway or pulmonary invasion, cutaneous disease or extrapulmonary dissemination. This section focuses on the invasive forms of aspergillosis. The inflammatory syndrome of allergic bronchopulmonary aspergillosis (ABPA) and allergic sinusitis is covered in the chapter titled "Hypersensitivity Pneumonitis and Eosinophilic Lung Diseases" (Chapter 65).

### Epidemiology

*Aspergillus* species are an important cause of life-threatening infection in immunocompromised children. Humans with normal pulmonary host defenses rarely develop IA, despite routine exposure to airborne conidia. It has been estimated that the average person inhales several hundred *Aspergillus* conidia spores per day.[37] Hospital construction and renovation have been linked to nosocomial infection in immunocompromised patients.[38] Specific groups of children are at risk of IA. This includes those with leukemia and other malignancies, neutropenia secondary to cytotoxic chemotherapy, HSCT, SOT, inherited or acquired immunodeficiencies, corticosteroid use, as well as low-birth-weight infants. In a retrospective study of pediatric patients with probable or proven IA, 63% had a hematologic malignancy, 38% had a history of a hematopoietic transplant, 11.5% had an inherited immunodeficiency, 6.5% had a history of a SOT and 0.7% had HIV infection.[39]

Of the primary immunodeficiencies, chronic granulomatous disease (CGD) has the best-characterized association with IA. There is a 33% lifetime risk of IA in CGD.[40] Severe combined immune deficiency (SCID) is the other primary immunodeficiency for which the risk of IA is known to be significant. Approximately 4% of children with SCID develop IA, resulting in a high mortality rate.[41]

Of the commonly used immunosuppressive medications, corticosteroids have been identified as an important risk factor for IA. Although the mechanisms are still incompletely understood, corticosteroids have been shown to impair the anticonidial activity of macrophages and suppress neutrophils, both in recruitment and antifungal activity.[42] Newer immunomodulating drugs that inhibit TNF have also been shown to increase the risk of pulmonary and IA.[17,43,44] There have also been reports of pulmonary aspergillosis in adults with critical illness secondary to influenza A H1N1.[45]

Aspergillosis has occasionally been described in premature neonates. In this population, risk factors for *Aspergillus* infection include skin maceration from adhesive tape or venous arm boards, percutaneous catheter insertion sites and necrotizing enterocolitis, all of which reflect mucocutaneous portals of entry.[46]

## Etiology

Species within the genus *Aspergillus* are ubiquitous worldwide; they are found in soil, water, air, and decaying vegetation. The classification of the genus *Aspergillus* is complex, as there are more than 200 different species that are divided amongst multiple subgenera.[47] Given that some species can be distinguished only by molecular typing, it has been proposed that isolates are referred to as a "species complex." *Aspergillus fumigatus* is a species complex that causes the majority of invasive disease in humans, and most of what is known about *Aspergillus* virulence factors and host immune response comes from research on this organism. *Aspergillus flavus* is the principal species found in sinusitis and accounts for up to 10% of all invasive isolates. *Aspergillus niger, Aspergillus terreus,* and *Aspergillus nidulans* are less common causes of invasive disease. *Aspergillus terreus* is a notable species given that it is resistant to amphotericin B, and infection from this organism is associated with a high mortality rate. *Aspergillus nidulans* has been found to occur at an unusually high frequency in children with CGD.[48] The varying pathogenicity of these different species is thought to be related to variables such as the ability to grow at 37°C, conidial size, growth rate, and the production of various virulence factors.

The infective components of the organism are conidia, which are readily aerosolized from the end of hyphal stalks. Inhalation and subsequent germination of conidia leads to the formation of hyphae in the distal airways. These hyphal forms of *Aspergillus* subsequently invade pulmonary blood vessels and parenchyma, resulting in thrombosis and ischemic necrosis of the affected lung. The time required for this sequence of events to occur is variable; the incubation period of IA is estimated to be as short as 2 days and as long as 3 months. After invasion of pulmonary tissue, spread to contiguous thoracic structures or hematogenous dissemination may occur.[49]

## Pathology/Pathogenesis

Anatomic barriers play an important role in the host defense against inhaled *Aspergillus* conidia. An intact respiratory mucosa, bronchial mucus, surfactant, and ciliated respiratory epithelium eliminate inhaled conidia and prevent germination. Innate immunity is clearly another important part of the host defense. Alveolar macrophages are responsible for the ingestion of conidia. Neutrophil recruitment and activation of cellular immunity also play key roles in the control of invasive hyphae. Once the *Aspergillus* conidia have germinated into invasive hyphal forms, vascular invasion is seen. One of the histopathologic hallmarks of IA is tissue infarction and necrosis.[41]

## Clinical Features (Symptoms/Physical Findings)

IA can be classified into four main clinical presentations: pulmonary aspergillosis, tracheobronchitis, rhinosinusitis, and disseminated disease. Of all these clinical presentations, invasive pulmonary aspergillosis (IPA) is the most common. In a study of aspergillosis in children with cancer, 70% of the 66 children with culture-proven disease had lung involvement.[50] In children with either CGD or HIV/AIDS, pulmonary disease is also the most common manifestation.[40,51] The classic triad of presenting symptoms for IPA is fever, pleuritic chest pain and hemoptysis, although this triad is seen in only a minority. More often, the presenting symptoms of IPA in children are nonspecific, with the most common complaints being fever, cough, and dyspnea.[50]

*Aspergillus* tracheobronchitis has been described in lung transplant recipients and those with other immunocompromising conditions. These patients present with cough, dyspnea, and wheezing. Three different patterns of *Aspergillus* tracheobronchitis have been described: obstructive, ulcerative, and pseudomembranous. Patients with obstructive tracheobronchitis have thick mucus plugs obstructing the airways, which consist of *Aspergillus* hyphae. These patients often present with expectoration of mucous plugs. Ulcerative tracheobronchitis represents the focal invasion of the mucosa and/or cartilage with *Aspergillus* hyphae. A final pattern is pseudomembranous tracheobronchitis, which is characterized by diffuse inflammation and invasion of the airway mucosa. This inflammatory process results in a pseudomembrane composed of necrotic debris from *Aspergillus* hyphae.[52]

Invasive rhinosinusitis due to aspergillosis can cause disease similar to mucormycosis. This can present acutely with fever, facial pain, epistaxis, and visual changes. Extension into the orbits and CNS can be seen. Early nasal endoscopic evaluation by an otolaryngologist is important in the immunocompromised patient, where necrotic lesions are seen from fungal invasion of the mucosal tissues. Disseminated aspergillosis can spread from the respiratory tract to multiple different organs including the skin, CNS, eyes, liver, and kidneys. *Aspergillus* spp. can also cause endocarditis, particularly in those with prosthetic heart valves.[49]

## Imaging, Pulmonary Function Testing, Laboratory Findings

The radiographic appearance of IPA is variable. Overall, the most common findings on plain radiographs of the chest are peripherally distributed lung nodules or masses.[53] Chest radiographs can also be normal early in diagnosis, or they may show a variety of nonspecific findings such as segmental or multilobar consolidation, perihilar infiltrates, pleural effusions or nodular lesions.[54] Chest CT is the imaging modality of choice for early diagnosis and has allowed for earlier preemptive therapy for patients at high risk for IA. Classic CT findings of the “halo sign” (a distinct nodular lesion with surrounding areas of decreased attenuation) and the “air crescent sign” (a late finding of nodular cavitation, usually occurring after recovery of neutrophil counts) are less common in children with IPA than in adults.[36,39] In a large retrospective study of children with IA, only 11% demonstrated the halo sign and 2.2% showed the air crescent sign.[39]

## Diagnosis

The diagnosis of IA involves multiple testing modalities including fungal culture of various clinical specimens, histopathologic examination of tissue, imaging studies and serum biomarkers such as the galactomannan assay.[55] The definitive diagnosis of IA requires the growth of *Aspergillus* spp. on culture in addition to the visualization of tissue-invasive hyphal forms from biopsy tissue obtained from the same organ (e.g., lung tissue and culture of airway secretions; see Fig. 31.3A and B). Given that humans are exposed to *Aspergillus* conidia on a daily basis, a positive culture of *Aspergillus* spp. from the airways does not necessarily indicate infection. Although lung biopsy is a valuable tool in the diagnosis of IPA, the risks involved in obtaining a biopsy makes this technique unfeasible in some children. For patients at risk of IPA who also have clinical and radiographic findings consistent with the diagnosis, the detection of *Aspergillus* spp. from respiratory tract secretions has been used as a surrogate method of diagnosis.[49]

When respiratory specimens are obtained from sputum or bronchoalveolar lavage fluid, both direct examination for hyphal elements (via staining with calcofluor or methenamine silver) and fungal culture should be performed. Growth of *Aspergillus* in the laboratory typically requires 1–3 days of incubation. Once growth is seen, identification of the species requires sporulation so that the spore-bearing structures can be seen on microscopy. If growth of *Aspergillus* spp. is present in culture and patients are suspected to have an azole-resistant isolate or are unresponsive to initial antifungal agents, susceptibility testing can be performed.[49]

Although a negative culture from sputum or BAL fluid cannot rule out the diagnosis, a positive culture in a neutropenic or bone marrow transplant (BMT) patient with new pulmonary infiltrates is putative evidence of IPA. However, in solid-organ transplant patients, nonneutropenic patients with chronic lung disease, and HIV-infected patients, the positive predictive value of respiratory tract cultures is much lower. There is evidence that the overall culture isolation rate of *Aspergillus* spp. from BAL or bronchial washing specimens is higher than that from biopsy tissue specimens (8.1% vs. 1.5%).[56]

When lung biopsy is performed, tissue from both the peripheral and central areas of the affected lung should be sampled. Thoracoscopic lung biopsy for diagnosis of IPA has not been systematically studied in children but has been used in this population. Given that biopsy is often not possible, due to comorbidities such as thrombocytopenia, alternative methods of diagnosis are needed in patients at risk of aspergillosis. Despite the angioinvasive nature of *Aspergillus* spp., positive blood cultures for the mold are rarely reported in IA.[56]

Various biomarker assays have been developed to help in the diagnosis of IA, including the galactomannan assay, PCR-based assays, and tests to detect the (1-3)-β-D-glucan found in the fungal cell wall. The galactomannan antigen assay uses a double-sandwich EIA to detect galactomannan, a polysaccharide cell wall antigen of *Aspergillus* spp. The assay recognizes circulating galactomannan in patients with IA and was approved in 2003 for use in the United States on serum and BAL specimens.[49] The galactomannan assay is best validated for neutropenic patients with hematologic malignancy and HSCT. In some of the early studies, the galactomannan antigen assay was reported to have a sensitivity as high as 81% and a specificity as high as 89%.[57] Subsequent studies in more diverse populations have shown significantly more variability in test sensitivity, with rates ranging from 30% to 100%.[58] Data on the galactomannan assay in children are limited. In a retrospective study of children receiving chemotherapy or those with a history of HSCT, the galactomannan antigen assay showed poor sensitivity (32%) and positive predictive value (70%), but good specificity (98%) and negative predictive value (92%).[59] Variables such as cutoff values for positivity, specimen treatment, preceding antifungal treatment, pretest probability of IA based on risk factors, and false-positive results in patients receiving piperacillin/tazobactam are thought to contribute to the variability of the results.[58,60]

Detection of *Aspergillus* spp. in BAL fluid has been studied using the galactomannan assay and PCR technology, but the precise role of these techniques in diagnosis remains to be seen. In a study of 85 children (59 of whom were immunocompromised), the use of the galactomannan assay on BAL fluid showed a sensitivity of 78% and specificity of 100% for pulmonary aspergillosis.[61] In a study of adult patients with hematologic malignancies, the authors found that the galactomannan assay of BAL fluid had a sensitivity of 92% and specificity 98%.[62] In the same study, PCR of BAL fluid for *Aspergillus* spp. was compared to the galactomannan assay. The authors found that PCR showed a decreased sensitivity compared with the galactomannan assay but had a similar specificity. *Aspergillus* PCR from blood specimens of immunocompromised patients has also been studied. In a meta-analysis of 18 primary studies (4 of which included pediatric patients), the authors found that the *Aspergillus* blood PCR had a mean sensitivity and specificity of 80.5% and 78.5% when tested in patients at high risk of IA. The authors also found a high negative predictive value of 96%.[63]

Several assays (e.g., Fungitel, Fungitec, and Endosafe-PTS) have been developed to detect another component of the fungal cell wall, (1-3)-β-D-glucan (BDG). As a nonspecific marker of invasive fungal infections, BDG assays have varying predictive values in studies of adult patients. However, the assay does not distinguish *Aspergillus* from the other fungi that contain BDG (various other molds, *Candida* spp., *Pneumocystis*). Furthermore, the performance of the BDG assays in pediatric patients is largely unknown.[36]

## Differential Diagnosis

IA can mimic multiple other disease processes depending on the clinical and radiographic features. Pulmonary aspergillosis can be difficult to distinguish from tuberculosis or other invasive fungal infections (e.g., mucormycosis, *Fusarium* spp.). Rhinosinusitis due to *Aspergillus* spp. can be clinically and radiographically similar to invasive mucormycosis.[49]

## Management and Treatment

Effective treatment of IA involves a combination of antifungal therapy, reversal of immunosuppressing drugs or interventions and in some cases surgery. For over 40 years, amphotericin B was recommended as primary therapy for IA.[65] Monotherapy with amphotericin B has historically had only modest success in the treatment of IA. Mortality with amphotericin B as sole therapy for IA was 65% in one large retrospective review.[49] The toxicity of amphotericin B deoxycholate is well known, with nephrotoxicity being the most common dose-limiting side effect. The newer lipid formulations of amphotericin B offer reduced toxicity, but these compounds have not shown an increase in efficacy relative to the deoxycholate formulation.

In a seminal randomized trial published in 2002, primary therapy with voriconazole was shown to be superior to amphotericin B.[66] Subsequent studies have supported this conclusion, with an estimated 15% improved survival at 12 weeks in patients who received voriconazole compared with other antifungal therapies.[49] The IDSA guideline on the management of aspergillosis published in 2016 recommends that voriconazole be used as the primary treatment of IA in adults and children. The intravenous form should be used for patients with severe illness. When the oral form is used, trough levels should be greater than 1–1.5 μg/mL for efficacy but less than 5–6 μg/mL. Treatment should continue for a minimum of 6–12 weeks, depending on the duration of immunosuppression and evidence of disease improvement. Isavuconazole has shown promise as a treatment option for IA, as it is associated with a lower rate of hepatobiliary and visual disturbances as compared with voriconazole. In a randomized double-blind trial comparing voriconazole with isavuconazole in 527 adults with invasive mold infections (primarily with *Aspergillus* spp.), isavuconazole was found to be noninferior to voriconazole.[67] Based on these data, isavuconazole was approved by the FDA as an alternative primary therapy for IPA. Amphotericin B should still be used for situations in which hepatic toxicities or drug interactions warrant an alternative to azoles or when voriconazole-resistant molds (e.g., mucormycosis) are still in the differential diagnosis.[49]

Primary therapy with an echinocandin is not recommended for aspergillosis unless the patient is intolerant to both the azoles and amphotericin B or has failed alternative therapy (i.e., salvage therapy).[49] The combination of either voriconazole or amphotericin

B with an echinocandin shows some evidence of benefit based on in vitro studies and small nonrandomized clinical trials.[68,69] The authors of the IDSA guideline recommend that combination antifungal therapy be reserved for severe disease, especially in patients with profound and persistent neutropenia.[49]

Treatment of IA should involve the reduction or elimination of immunosuppressive agents when possible. Adjunctive therapies such as interferon gamma (INF-$\gamma$), colony-stimulating factor, and infusions of granulocytes harvested from donors pretreated with granulocyte colony-stimulating factor (GCSF) have a role in the treatment of aspergillosis in certain patients. Although these modalities have not yet been well studied, experience with certain patient populations has led to recommendations for their use. GCSF or granulocyte macrophage colony-stimulating factor (GM-CSF) should be considered in severely neutropenic patients who do not respond to standard therapy. Granulocyte transfusions can be considered for patients with prolonged neutropenia and disease that is refractory to standard therapy. In patients with CGD, recombinant INF-$\gamma$ is recommended as prophylaxis against IA and other infections.[49]

Therapeutic surgical excision of IPA also has a role in the treatment of certain patients. Surgical resection can provide a definitive diagnosis and can completely eradicate a localized infection of the lung. Patients with IPA that has invaded the great vessels, pericardium, or pleural space may also benefit from surgical intervention. In a retrospective review of 43 pediatric patients with IPA, most of whom were significantly immunosuppressed, the authors found a significantly higher survival rate in the 18 patients who underwent surgical intervention compared with those who received only medical therapy.[70] The retrospective nature of the study, high overall mortality rate in the series (91%) and limitations of medical therapy available at the time of the study (i.e., before the approval of voriconazole) make it difficult to know if such findings can be generalized to current care. In the absence of chest wall extension or uncontrolled bleeding, there is no consensus regarding the benefit of surgical resection prior to HSCT or intensive chemotherapy. General recommendations for the treatment of aspergillosis were published in 2016 by the IDSA.[49]

## Prevention

Children with prolonged neutropenia who are at risk of IA should receive prophylaxis with posaconazole or voriconazole. For children previously treated for IA who will require subsequent immunosuppression, antifungal therapy should be restarted to prevent recurrent infection. Children who have had a lung transplant should receive antifungal prophylaxis for 3–4 months after lung transplant with either an azole such as voriconazole or itraconazole or inhaled amphotericin B. Hospitalized allogeneic HSCT recipients should be roomed in a protected environment to reduce exposure to mold. Routine environmental sampling of fungal spores in the hospital is not recommended in the absence of a known outbreak.[49]

## Prognosis

In a retrospective analysis of 139 children with IA, the overall mortality rate was found to be 52.5%. The highest mortality rate was seen in patients with allogeneic HSCT, where 78% of the patients had died by 12 weeks or at the end of therapy.[39]

# Candidiasis

## Epidemiology

Invasive infections due to *Candida* species can cause significant morbidity and mortality in certain populations of children. *Candida* spp. are the third most common cause of nosocomial bloodstream infections in children.[71] Risk factors include the use of broad-spectrum antibiotics, invasive devices such as central venous catheters, organ transplant, immunosuppressive chemotherapy regimens, and neonates born with very low birth weights. Infections occur primarily via tissue invasion from endogenously acquired strains rather than by person-to-person spread.

## Etiology

*Candida* spp. are yeasts that reproduce by budding. Most members of the genus can produce only pseudohyphae, which are chains of elongated yeast that result from incomplete budding. An exception to this is seen with *Candida albicans* and *Candida dubliniensis,* which can produce true hyphae under conditions found in the human host.

*Candida* spp. commonly colonize the human gastrointestinal tract, genital mucosa and skin. Of the approximately 150 known species of *Candida,* only 15 species are known to cause human disease.[72] *C. albicans* is by far the most common species to cause disease and represents about 50% of pediatric invasive candidiasis.[73] Other important *Candida* species include *Candida krusei, glabrata, parapsilosis, tropicalis, lusitaniae* and *dubliniensis.*

## Pathology/Pathogenesis

Most studies related to the pathogenicity of *Candida* spp. have utilized *C. albicans.* This microorganism has several notable virulence factors including adhesion to host mucosal cells, morphologic switching between the yeast and hyphal forms and the ability to form biofilms. The formation of biofilms plays a significant role in infections of medical devices including central venous catheters and cardiovascular devices. The immune response to *Candida* is complex and involves the innate and adaptive arms. Neutrophils, macrophages, and monocytes play a particularly important role in preventing disseminated candidiasis, as evidenced by the high risk of disseminated disease in neutropenic patients.[74]

## Clinical Features (Symptoms/Physical Findings)

*Candida* spp. are well known for their ability to cause mucocutaneous infections in normal hosts, including oral-pharyngeal (thrush) infection, diaper rash and paronychia. Immunocompromised patients can develop laryngeal or esophageal candidiasis. Disseminated or invasive candidiasis can occur in almost any organ system or anatomic site. In children with disseminated candidemia, the lungs were found to be involved in 45%–58% of cases. Less common sites of dissemination include the liver, kidney, brain, heart, spleen, and eyes.[74,75]

When pulmonary candidiasis does occur, three different patterns of disease have been described: primary pneumonia due to tracheobronchial colonization and aspiration, secondary pneumonia in the setting of candidemia with disseminated disease, and secondary pneumonia in the setting of septic emboli.[76] In all of these cases, the clinical manifestations are nonspecific, with fever, cough, and a sepsis-like picture being the most common presentation. Primary candidal pneumonia (i.e., with no evidence of candidemia or other sites of disseminated disease) is rare and is thought to be limited to neutropenic patients and low-birth-weight infants. In patients with disseminated disease, bilateral lung involvement is typical, and microscopic examination of the lung shows pseudohyphae in the pulmonary capillaries. In embolic disease, the lungs (and other organs) are seeded with infected emboli from an endovascular source, resulting in hemorrhagic infarcts at the periphery of the lungs. Invasive candidiasis in neonates differs from disease in older children in that neonates are more likely to present with nonspecific or subtle signs and symptoms of infection.[73]

## Imaging, Pulmonary Function Testing, Laboratory Findings

Patterns on chest radiographs have been described most often as patchy consolidations, with larger areas of consolidation limited to severe disease. Nodular lesions with central necrosis can be seen in disseminated disease and are best detected by CT of the lungs. Cavitation and pleural effusions are rare findings.[53]

## Diagnosis

*Candida* grows well on routine agar and does not require specialized fungal media. Culture of *Candida* spp. from a sterile body site (e.g., blood or CSF) or the demonstration of organisms from tissue biopsy are still the “gold standard” for diagnosis. Growth is typically seen after 2–3 days of incubation, but occasionally >7 days. Automated blood culture systems can allow for earlier detection, but overall sensitivity of candidemia by blood culture is still less than 50%.[77] There are multiple nonculture diagnostics for invasive candidiasis (BDG, antigen/antibody detection assays, PCR), but none are currently recommended by the IDSA guideline for routine use in children.

In immunocompetent children, growth of *Candida* spp. from the sputum or tracheostomy cultures usually indicates colonization and not infection. In a study of nonneutropenic patients, nearly 90% of bronchoalveolar lavage cultures positive for *Candida* spp. were judged to be probably or definitely contaminated, despite the fact that the majority of the cultures had been done on protected brush specimens.[78] Candidal pneumonia after aspiration is rare in immunocompetent children.

In immunocompromised patients, growth of *Candida* from a respiratory tract culture should prompt clinicians to investigate for invasive candidiasis, although it can be difficult to distinguish oropharyngeal or tracheobronchial colonization from invasive pulmonary disease. In a large study of adult cancer patients, the positive predictive value of various cultures for pulmonary candidiasis was determined using histopathology from autopsy specimens as the gold standard. The authors found that the positive predictive value of a sputum culture for pulmonary candidiasis was 42%; from BAL fluid culture it was 29%.[79]

In intubated patients, histologic evidence of candidal invasion of the lung tissue is the only widely accepted definition of pulmonary candidiasis.[76] In patients with candidemia and new respiratory symptoms or radiographic abnormalities, the diagnosis of invasive pulmonary candidiasis should be strongly suspected.

## Differential Diagnosis

Invasive candidiasis, depending on the organ system involved or the clinical situation, can mimic multiple disease processes. Candidemia can mimic septic shock. Pulmonary candidiasis can be confused for bacterial or viral pneumonia or other pulmonary mycoses such as aspergillosis or cryptococcosis.

## Management and Treatment

The approach to the treatment of invasive candidiasis depends on a variety of factors including the status of the host immune system, source of infection (e.g., medical device–associated, endovascular), identified *Candida* spp. susceptibility profile, and age of the patient.

For neonates with invasive candidiasis, treatment recommendations differ from those for non-neonates given the distinct epidemiology and pathogenesis of the disease in this population as well as the distinct pharmacokinetic and pharmacodynamics of antifungal drugs.

Multiple antifungal drug classes play a role in the treatment of invasive candidiasis, each with strengths and weaknesses based on the clinical scenario. These drug classes include the polyenes (amphotericin B), the azoles, the echinocandins, and flucytosine. Amphotericin B is effective against most *Candida* species with notable exceptions being resistance in *C. lusitaniae* and decreased susceptibly in *C. krusei and C. glabrata.* As mentioned in the section on antifungal drugs at the beginning of this chapter, the lipid preparations of amphotericin B are generally recommended over the deoxycholate form. In the azole family of antifungals, fluconazole should not be used prior to identification of the *Candida* species, as *C. krusei* is resistant to fluconazole and increasing rates of resistance have been seen with *C. glabrata* (~50%) and *C. tropicalis.* Other drugs in the azole family have broader anticandidal activity than fluconazole, but resistance is still seen in some cases (e.g., voriconazole is often ineffective against *C. glabrata*). The echinocandins (caspofungin, micafungin, and anidulafungin) have good activity against almost all *Candida* species, have a good safety profile, and are approved as first-line agents for severely ill or neutropenic patients. Of note, there is an overall trend of increasing resistance of *Candida* species to the triazoles and echinocandins.[80] The use of flucyctosine is generally limited to children with candidal infections of the CNS. Therapeutic drug monitoring may be needed in patients on itraconazole, voriconazole, posaconazole, and flucytosine. Standards for susceptibility to the triazole and echinocandin antifungals have been established for *Candida* spp., and testing is available commercially.

Outside the neonatal population, nonneutropenic children with invasive candidiasis can be treated with fluconazole or an echinocandin. In neutropenic patients or those with critical illness, an echinocandin or liposomal amphotericin B should be used. Voriconazole can be used in children in situations where additional mold coverage is needed. In both of these situations, fluconazole can be used as step-down therapy for patients who have susceptible isolates and documented blood culture clearance.

In patients with a vascular or peritoneal catheter, removal of the catheter is recommended, in addition to antifungal therapy. Full details of management of patients with candidal infection of central venous catheters can be found in guidelines published by the IDSA.[81] In patients with persistent disease despite adequate treatment, a search for a disseminated infection should be conducted. This diagnostic evaluation may need to include evaluation of the liver, spleen, lung, heart, and genitourinary tract. The length of treatment for patients without metastatic complications is generally 2 weeks after clearance of the bloodstream and resolution of symptoms. In disseminated candidiasis, other sites of infection may dictate the type and length of treatment (e.g., endocarditis, meningitis, endophthalmitis). All patients with candidemia should have a dilated fundoscopic evaluation. A lumbar puncture is recommended for all neonates with candidemia.[82]

In neonates with invasive candidemia, amphotericin B deoxycholate is the drug of choice with disseminated disease, including meningitis. The lipid formulations of amphotericin B should be used with caution in neonates, especially if urinary tract involvement is suspected. Oral or IV fluconazole is an alternative to amphotericin B deoxycholate in patients who have not been on fluconazole prophylaxis. The echinocandins should be used with caution in neonates because there are limited data in this population. The IDSA guidelines recommend that this class of antifungals should be limited to salvage therapy or to situations in which resistance or toxicity preclude the use of amphotericin B or fluconazole.[73]

Full details of the treatment of neonatal and nonneonatal candidemia can be found in the guidelines published by the IDSA. These guidelines were last published in 2016 and were endorsed by the American Academy of Pediatrics (AAP) and the Pediatric Infectious Diseases Society (PIDS).[73]

## Prevention

Fluconazole prophylaxis is recommended for infants of extremely low birth weights who are admitted to a neonatal intensive care unit with at least moderate rates (≥5%) of invasive candidiasis. Prophylactic fluconazole is also sometimes used in patients with advanced HIV disease, allogenic HSCT, and severe neutropenia.[82]

## Prognosis

The mortality rate of invasive *Candida* infection in neonates is high. In a multicenter study of infants weighing less than 1000 g at birth, the mortality rate was 34% in those with invasive candidiasis, compared to 14% in those without invasive candidiasis.[83] Outside the neonatal period, children with candidemia were also found to have a significant mortality rate. In studies of candidemia in children of all ages, mortality rates range from 10% to 28%.[71,84,85]

# Cryptococcosis

## Epidemiology

*C. neoformans* and *Cryptococcus gattii* are two species of *Cryptococcus* known to be human pathogens. *Cryptococcus* is an encapsulated yeast that is found worldwide. Exposure to soil that has been contaminated with bird excrement has been found to be associated with infection. In the pre-AIDS era, symptomatic cryptococcal disease (cryptococcosis) was thought to be an uncommon condition, primarily associated in those with hematologic malignancies or recipients of organ transplants. In the HIV era, rates of cryptococcal disease increased significantly. Currently cryptococcosis is most associated with HIV infection, with an estimated 1 million new cases a year worldwide.[86]

Cryptococcosis is an AIDS-defining illness and is seen most often in HIV-infected patients with CD4$^+$ lymphocyte counts fewer than 100/μL. In adults with AIDS, cryptococcosis occurs in approximately 5% of patients annually. In children with AIDS, this rate is significantly lower, with reported rates of approximately 1% annually.[87] Reasons for the lower incidence in children with AIDS are not known, but potential reasons include a decreased number of lifetime exposures, differences in infecting strains, and inadequate time to reactivate a prior infection.[88] *C. neoformans* infection in children is also associated with leukemia, lymphoma, prolonged courses of corticosteroids, and SOT as well as in those with congenital immunodeficiencies such as hyperimmunoglobulin M (IgM) and hyperimmunoglobulin (IgE) syndromes.

Cryptococcosis has also been found to occur in immunocompetent children. In a study utilizing a national database of 42 children's hospitals from the United States, the authors identified 63 children who were hospitalized with cryptococcal disease between 2003 and 2008. Of these children, 64% had an immunocompromising medical condition, 21% were immunocompetent, and 16% had HIV.[89] In another study from Colombia, the authors identified 41 children with the diagnosis of cryptococcosis from 1993 to 2010. Of this cohort, 24.4% had AIDS and 46.3% had no known risk factors.[90]

The incubation period for *C. neoformans* has not been determined, as infection with this organism often represents reactivation of latent disease. The incubation period for *C. gattii* is 2–13 months.[82]

## Etiology

*Cryptococcus* is a polyphyletic genus of encapsulated yeasts that compromises more than 70 species. Two of these species, *C. neoformans* and *C. gattii,* are known to be pathogenic in humans. *C. neoformans* primarily causes disease in immunocompromised patients and represents 90% of infections worldwide. *C. gattii* also causes disease in immunocompromised patients but is more likely than *C. neoformans* to cause illness in immunocompetent hosts. This phenomenon recently gained attention when *C. gattii* was found to be the cause of disease in otherwise healthy hosts in the Pacific Northwest of the United States and adjacent parts of Canada.[91]

*Cryptococcus* has been isolated from soil, trees, and fruit. Dried pigeon droppings have been found to be a particularly effective culture medium for *Cryptococcus* spp. *C. neoformans* grows as yeast and replicates by budding. The organism's sexual state creates basidiospores at the end of the hyphae. The basidiospores are aerosolized and can be inhaled by humans. After inhalation, the organism initially grows in the alveoli without a significant inflammatory response, which is thought to be due in part to the antiphagocytic effect of the polysaccharide capsule. Once within the lung, *Cryptococcus* may either be contained in a dormant state or disseminate to other organs prior to an adequate host immune response. The CNS is a common site of dissemination for *C. neoformans,* although the reason for this CNS tropism is not known.[92]

## Pathology/Pathogenesis

Both innate and adaptive immune responses are necessary to control infection due to *C. neoformans.* T cells activate alveolar macrophages via cytokines and promote ingestion of the encapsulated yeast. Humoral immunity plays a role in opsonization, activation of natural killer cells, and clearing of capsular polysaccharide. Conditions associated with defective cellular immunity are at increased risk of symptomatic cryptococcal infections.[92]

## Clinical Features (Symptoms/Physical Findings)

Although the most common route of acquisition of cryptococcosis is via inhalation, the pulmonary manifestations of the disease are often mild or asymptomatic.[93] It is estimated that less than 10% of patients with disseminated cryptococcosis have pulmonary symptoms at the time of diagnosis.[92] In individuals with symptomatic pulmonary disease, the typical presentation includes fever, cough, pleuritic chest pain, and weight loss. In cases of disseminated cryptococcosis, virtually any organ system can be involved. The most important sites of extrapulmonary infection include the CNS, skin, prostate and eyes. Cryptococcal meningitis often presents in an indolent manner with progressive symptoms of fever, headache, visual changes, and altered mental status. Isolated cryptococcal fungemia without concurrent organ involvement can occur in adults with HIV but is rare in children.[82]

## Imaging, Pulmonary Function Testing, Laboratory Findings

For patients with pulmonary cryptococcal infection, imaging of the chest by plain radiographs and CT is usually nonspecific. An isolated pulmonary nodule, with or without hilar adenopathy, may be the only manifestation of pulmonary cryptococcal infection in immunocompetent individuals. In patients with more severe manifestations of pulmonary cryptococcosis, a variety of imaging findings have been well described, including multiple lung nodules, lobar consolidation with a predilection for the lower lobes, cavitary lesions, pleural effusion, diffuse interstitial infiltrates, and an ARDS-like appearance.[92,94] If signs of increased intracranial pressure or CNS infection are present, magnetic resonance imaging (MRI) or CT of the head to rule out hydrocephalus and cryptococcomas is indicated. In patients with CNS disease, common CSF indices such as cell count, protein and glucose values can be normal.

## Diagnosis

The sensitivity of diagnostic tests for cryptococcal disease are different depending on whether there is isolated pulmonary disease or disseminated disease. For disease isolated to the lungs, noninvasive diagnostic tests have a relatively low sensitivity. Serum cryptococcal antigen testing is usually negative in isolated pulmonary disease. Likewise, sputum culture has a low sensitivity. Bronchoscopy with fungal culture and antigen testing of the lavage fluid can be helpful, although the sensitivity of this approach is variable for patients with isolated pulmonary cryptococcosis.[93] Antibodies to *C. neoformans* can develop in response to either colonization or infection and are not useful in diagnosis.[92]

Given the limitations of noninvasive methods for isolated pulmonary cryptococcal disease, more invasive procedures such as transthoracic or transbronchial fine-needle aspiration or open lung biopsy may be required to confirm the diagnosis. Direct histopathologic identification of *C. neoformans* from tissue biopsy specimens is both sensitive and specific for the diagnosis of isolated pulmonary disease. Several different stains can be used to identify the yeast in tissue, including silver stains or stains that target the polysaccharide capsule (e.g., mucicarmine stain).[92] Caution should be used in interpreting the significance of growth of *Cryptococcus* from sputum culture, as this may represent colonization.[95]

Cryptococcus can be grown on standard automated blood culturing systems, although growth is best seen with Sabouraud dextrose agar. This media can be used to culture the organism from tissue, sputum, blood, BAL fluid, or CSF. Growth can be slow, sometimes taking up to a week for cultures to become positive. When pleural effusions are present, cultures of thoracentesis fluid are positive in about 40% of AIDS patients.[95] Selective media are available to differentiate *C. neoformans* and *C. gattii.* Susceptibility testing for cryptococcal organisms is available, although resistance to antifungals is uncommon.

In contrast to patients with cryptococcal pulmonary disease, the diagnosis of cryptococcal meningitis is less difficult. The latex agglutination test and EIA can be used to provide a rapid diagnosis for those with suspected meningitis. All of these tests detect cryptococcal capsular polysaccharide antigen and are approved for use on serum or cerebrospinal fluid. The sensitivity of these antigen assays in patients with cryptococcal meningitis is greater than 90%. Visualization of encapsulated yeast cells in CSF using India ink has sensitivity ranging from 50% to 80%. Given the frequency of concomitant meningitis, it is generally recommended that a lumbar puncture be performed on patients with pulmonary disease even in the absence of overt signs of CNS infection.[92]

Patients who are severely immunocompromised with cryptococcal disease have been found to have significant incidence of coinfection with other pathogens such as *Mycobacterium tuberculosis,* nontuberculous mycobacteria, cytomegalovirus, *Nocardia* spp., and *P. jirovecii.* For this reason, patients with cryptococcal disease should be tested for additional pathogens as appropriate to the clinical situation.

## Differential Diagnosis

The differential diagnosis of a patient with suspected cryptococcal pulmonary disease depends on the clinical scenario and radiographic findings. Patients with an ARDS-like clinical picture and immunodeficiency may present like cases of *P. jirovecii* infection. Patients with an indolent course of fever, cough, and multiple pulmonary nodules on chest radiograph may be suspected to have a lung malignancy. Children with fever, cough, sputum production, and lobar consolidation are often treated for bacterial pneumonia prior to the diagnosis of pulmonary cryptococcosis.[96]

## Management and Treatment

There are no prospective trials in children for the treatment of cryptococcosis. The IDSA guideline on cryptococcosis makes treatment recommendations for both adults and children.[92] For otherwise healthy children with mild-to-moderate pulmonary cryptococcosis, fluconazole is recommended for 6–12 months. If fluconazole cannot be used, itraconazole, voriconazole, and posaconazole are effective alternatives. Echinocandins should not be used as they do not have activity against *Cryptococcus* spp. Children with severe pulmonary cryptococcosis should be treated similarly to those with CNS disease, regardless of immune status.

All immunocompromised patients and those with CNS cryptococcal infection should be treated aggressively. Corticosteroid treatment may be considered if ARDS is present. Immunocompromised patients with isolated pulmonary cryptococcosis that is mild to moderate in severity (i.e., absence of diffuse pulmonary infiltrates) can be treated with fluconazole orally for 6–12 months. For patients with cryptococcal meningitis, the preferred regimen for induction and consolidation therapy is amphotericin B deoxycholate plus oral or intravenous flucytosine for 2 weeks (or until CSF cultures are negative). This should be followed by oral fluconazole for a minimum of 8 weeks. Lipid formulations of amphotericin B can be substituted for deoxycholate formulations in children with abnormal renal function. After induction and consolidation therapy, maintenance (suppressive) or prophylactic therapy may be indicated depending on the immunosuppressing condition. The IDSA guidelines provided detailed recommendations regarding the length of maintenance and prophylactic therapy for children with HIV and other immunosuppressive conditions.[92]

## Prognosis

The prognosis for patients with isolated pulmonary cryptococcosis has not been studied thoroughly, but in the absence of dissemination outcomes appear to be favorable.[95] Prognosis in patients with cryptococcal meningitis is predicted by various CSF parameters, such as organism load, opening CSF pressure, CSF glucose and leukocyte count, and titers of cryptococcal antigen in

CSF or blood.[96]

# Mucormycosis (Formally Zygomycosis)

## Epidemiology

Mucormycosis is caused by environmental molds found primarily in soil and organic matter. The organism has a near worldwide distribution. The main route of transmission is inhalation of spores from an environmental source. Outbreaks of disease have been linked to construction, excavation, and contaminated air-conditioning filters. Nosocomial clusters of cutaneous infections have been traced to contaminated wooden tongue depressors and various adhesive bandages used in the hospital.[97] Ingestion of spores can also result in gastrointestinal disease. Invasive mucormycosis is typically limited to those with an impaired immune system. Diabetic patients, particularly during ketoacidosis, are known to be at risk for developing rhinocerebral mucormycosis.[98] In nonneutropenic HSCT recipients, mucormycosis can be seen as a late (1–6 months) or very late (>6 months) infection.[99]

## Etiology

As with many fungal pathogens, the taxonomy of these organisms has changed. The phylum name Zygomycota has been reorganized based on new molecular phylogenic analyses, and the species that cause human disease are no longer limited to this phylum. For this reason, the term *zygomycosis* is no longer considered valid. Given that the clinically significant causative agents of mucormycosis belong to the order *Mucorales,* the term mucormycosis has been proposed as the most valid mycologic reference.[98] Within the family of *Mucorales,* the most clinically significant genera are *Rhizopus* and *Mucor. Mucorales* are filamentous fungi that produce sporangiospores (asexual spores) contained within a saclike structure called a sporangium. When this structure ruptures, the sporangiospores are released and can be inhaled by the human host. Therefore sinus and pulmonary infections are the most common manifestation of this disease.

## Pathology/Pathogenesis

Both macrophages and neutrophils are responsible for controlling infection due to mucormycosis. Alveolar macrophages control the germination of inhaled spores through phagocytosis. Neutrophils and mononuclear cells also prevent germination via generation of oxidative metabolites. Dysfunction of macrophage phagocytosis, neutrophil chemotaxis, and oxidative killing by neutrophils have been demonstrated in diabetic ketoacidosis.[100] Other important risk factors include use of corticosteroids, broad-spectrum antibiotics, and hematologic and organ transplantation. One other established at-risk patient group are those receiving iron chelation therapy with deferoxamine. It is thought that this drug acts as a siderophore where it can deliver iron to the fungus, thus promoting growth.[101]

## Clinical Features (Symptoms/Physical Findings)

Mucormycosis can be classified into the following forms: rhinocerebral, pulmonary, cutaneous, gastrointestinal, and disseminated disease. Pulmonary disease is the most common clinical manifestation and is found to account for 30% of mucormycosis in a recent series from Europe.[102] The clinical symptoms of pulmonary mucormycosis can initially be subtle or nonspecific in immunocompromised patients. When symptoms are seen, children with pulmonary mucormycosis develop persistent fever, cough, chest pain, and dyspnea. The disease is sometimes found in at-risk patients with pulmonary infiltrates that persist despite treatment for presumed bacterial pneumonia. In advanced disease, hemoptysis can occur because of angioinvasion and hemorrhagic infarction, which characterize this group of infections. Clinicians should be especially alert to the possibility of mucormycosis in children who are receiving antifungal prophylaxis with agents that have activity against *Aspergillus* but not the *Mucorales* (e.g., voriconazole or the echinocandins).[99]

## Imaging, Pulmonary Function Testing, Laboratory Findings

The radiographic findings of mucormycosis are quite variable. Isolated nodules, lobar consolidation, cavitary lesions, wedge-shaped areas of infarction, and disseminated pulmonary involvement have all been described.[103]

## Diagnosis

The diagnosis of invasive mucormycosis is difficult, as the sensitivity of fungal cultures from blood and respiratory tract specimens is low. Testing modalities such as serology and antigen detection are not clinically useful for mucormycosis. PCR assays to detect *Mucorales* from tissue specimens have shown promise but have not yet become a standardized adjunctive diagnostic test.[104] A tissue-based approach is essential to the diagnosis assuming that the patient can tolerate the necessary procedure.[105] As with *Aspergillus* spp., histopathology performed on tissue specimens from patients with mucormycosis often shows angioinvasion, with resulting vessel thrombosis and tissue thrombosis.[99] Given these diagnostic limitations, a high index of suspicion is needed in at-risk patients to identify mucormycosis as early as possible. Unfortunately the diagnosis is often made after severe disease or at autopsy.

## Differential Diagnosis

Pulmonary mucormycosis can be difficult to distinguish from IPA. In patients with hematologic malignancies, factors that favor the diagnosis of mucormycosis are the presence of concomitant sinusitis, the presence of more than 10 pulmonary nodules, and multiple negative serum *Aspergillus* galactomannan antigen assays. The diagnosis of mucormycosis is favored if the patient was receiving prophylactic antifungal agents with activity against *Aspergillus*, such as voriconazole or echinocandins.[106]

## Management and Treatment

Treatment of mucormycosis involves a combination of antifungal therapy, aggressive debridement of necrotic lesions, and, when possible, reversal of the predisposing condition that originally led to the infection. Amphotericin B (lipid formulation if available) is the recommended antifungal in patients with mucormycosis. In a study of 70 patients (primarily adults) with hematologic malignancy who had mucormycosis, the authors found that a delay of 6 or more days of an amphotericin B–based therapy resulted in a twofold increase in mortality rate compared with early treatment (82.9% vs. 48.6%).[107]

Most azoles and echinocandins lack significant activity against the organisms that cause mucormycosis, although a few notable exceptions have been found. Both posaconazole and isavuconazole have in vitro activity against the *Mucorales*.[108,109] There are multiple published reports of success with posaconazole as part of combination therapy or salvage therapy for mucormycosis.[110–113] Another exception has been found with caspofungin. Although caspofungin has no activity against the fungi that cause mucormycosis in standard in vitro susceptibility tests, there is some evidence in animal and human studies that caspofungin is synergistic with amphotericin B. In a study of diabetic ketoacidotic mice with disseminated mucormycosis, caspofungin combined with amphotericin B resulted in better outcomes than amphotericin B alone.[114] This combination of caspofungin combined with amphotericin B was also associated with improved outcomes in a retrospective study of primarily diabetic patients with rhino-orbital-cerebral mucormycosis.[115] Isavuconazole has been studied as primary or salvage treatment in adults with mucormycosis. In an open-label trial, the authors found that isavuconazole showed similar efficacy to historical controls who were treated with amphotericin B.[116]

The optimal length of treatment with antifungals has not been studied in patients with pulmonary mucormycosis. Most successfully treated patients require at least 4–6 weeks of therapy, although longer courses may be needed based on clinical response and ability to reverse the underlying immunocompromised state.

Mucormycosis is associated with tissue infarction; therefore antifungal therapy alone may not allow for clinical cure without debridement of devitalized tissue.[117] In a retrospective review of 255 cases of pulmonary mucormycosis, mortality of patients treated with debridement and antifungal therapy was significantly lower than those who received antifungal therapy alone.[118]

## Prognosis

Mucormycosis is associated with high mortality, with reported rates of 100% for disseminated disease, 76% for pulmonary disease, and 46% for rhinocerebral disease.[106]

# Sporotrichosis

## Epidemiology

Sporotrichosis is caused by the fungus *Sporothrix schenckii* and is seen most commonly in Central America, South America, and the Midwest of the United States. Cutaneous sporotrichosis is the most common form of the disease in both adults and children. Pulmonary sporotrichosis is typically seen in adult males with alcoholism or other chronic medical illnesses such as diabetes mellitus. Disseminated sporotrichosis is rare in children and is typically seen in those who are exposed to immunosuppressive therapy, prolonged treatment with corticosteroids, or in those with AIDS.[119]

## Etiology

*S. schenckii* is a dimorphic fungus with a worldwide distribution in soil and plant products such as straw, wood, and sphagnum moss. Direct inoculation of exposed skin is the most common form of exposure, especially among those working with thorny plants (e.g., florists or rose gardeners). Household transmission has also been attributed to domestic cats.[120] Pulmonary sporotrichosis is thought to be secondary to the inhalation of spores rather than part of disseminated infection. In immunocompromised children, dissemination can occur after cutaneous inoculation or from primary pulmonary infection.[119]

## Pathology/Pathogenesis

The immunological mechanisms involved in host control of *S. schenckii* infections are not well understood. It is thought that both humoral and cellular responses are involved in response to fungal surface and secreted antigens. The factors that influence localized versus disseminated disease include inoculum load, immune status of the host, virulence of the inoculated strain, and depth of traumatic inoculation.[120]

## Clinical Features

Sporotrichosis is most commonly a cutaneous or lymphocutaneous infection that manifests as a chronic, papulonodular lesion with or without central ulceration. It is often associated with regional lymphadenopathy. In addition to cutaneous disease, sporotrichosis can occasionally occur as pulmonary, osteoarticular or meningeal infection. The primary pulmonary form of sporotrichosis results in a granulomatous pneumonitis that often cavitates. Signs and symptoms of pulmonary disease include productive cough, fever, weight loss, and hemoptysis. The presentation can be subacute or chronic. Patients with multifocal sporotrichosis are much more likely to be immunocompromised.[121]

## Imaging, Pulmonary Function Testing, Laboratory Findings

Radiographs often reveal unilateral or bilateral cavitary lesions with associated parenchymal infiltrate. Hilar lymphadenopathy or pleural effusions are occasionally seen.

## Diagnosis

The diagnosis of children with the classic lymphocutaneous form of sporotrichosis is relatively straightforward, given its characteristic pattern of presentation. The diagnosis of pulmonary or disseminated disease can be more difficult given that pulmonary or osteoarticular presentation can mimic other disease processes. The gold standard of diagnosis of sporotrichosis is fungal culture. Tissue biopsy, sputum, or BAL fluid can be inoculated onto Sabouraud's dextrose agar and incubated at room temperature. Growth typically occurs within 5 days. Fungal staining can be performed on tissue or respiratory specimens, but the small number of fungal organisms may limit visualization. Serology is not used routinely in the diagnosis of sporotrichosis, as the available assays lack adequate sensitivity and specificity. PCR assays have been developed for identifying *S. schenckii* in tissue specimens, but they are not widely available.[119]

### Differential Diagnosis

The skin lesions of sporotrichosis can resemble *Nocardia brasiliensis*, cutaneous leishmaniasis, or mycobacterial infection. The differential diagnosis of disseminated disease depends on the clinical scenario and location of disease. Pulmonary sporotrichosis can mimic mycobacterial infections, histoplasmosis, or coccidioidomycosis.

### Management and Treatment

Treatment of sporotrichosis involves a combination of antifungal therapy and, in some cases, surgical excision. Amphotericin B is the preferred antifungal treatment for life-threatening or extensive pulmonary sporotrichosis. After the patient has shown a favorable response to amphotericin B, therapy can be switched to itraconazole to complete a total course of therapy of at least 12 months. Localized pulmonary disease, particularly cavitary lesions, should be treated with a combination of surgical excision and amphotericin B.[121] In children with less severe pulmonary disease, itraconazole administered for at least 12 months is recommended. Lifelong suppressive therapy with itraconazole may be required for patients with AIDS and other causes of immunosuppression. Serum levels of itraconazole should be measured after the patient has received this medication for at least 2 weeks so as to ensure adequate drug levels. It is recommended that serum itraconazole levels be greater than 1.0 mg/mL.[119]

### Prognosis

Cutaneous sporotrichosis responds well to antifungal therapy. Disseminated disease in immunocompromised children can be difficult to treat and is associated with significant morbidity and mortality.

## Trichosporonosis

### Epidemiology

*Trichosporon* infections are caused by a group of related fungi that can occasionally cause invasive infections in humans. *Trichosporon* spp. have been found to colonize the gastrointestinal tract, respiratory tract, skin and vagina. Opportunistic invasive infections are thought to result from preexisting *Trichosporon* spp. that colonizes these locations. Invasive trichosporonosis can occur in patients with hematologic malignancies and other immunosuppressive states. This pathogen has also been proposed as a cause of severe exacerbations in patients with cystic fibrosis.[122] Immunocompetent patients typically have disease that is limited to the skin, nails or mucosal surfaces.[123]

## Etiology

*Trichosporon* species (*asahii, mucoides, mycotoxinivorans* and others) and the closely related *Blastoschizomyces capitatus* are related fungi that can occasionally cause disease in humans. For the purposes of this chapter, we will refer to these fungi collectively as *Trichosporon* species. These fungal organisms are commonly found in soil but can colonize the skin, hair shafts, sputum, and mucosal surfaces.

## Pathology/Pathogenesis

Invasive infection from *Trichosporon* spp. is thought to begin with cutaneous and mucosal endogenous flora. Alteration of integrity of these surfaces by an intravascular catheter or chemotherapy-induced mucosal injury may lead to bloodstream infection. Some *Trichosporon* spp. can form biofilms on implanted devices.[124]

## Clinical Features (Symptoms/Physical Findings)

Disease in immunocompetent patients is usually limited to the superficial infections of the skin and hair shafts, particularly in tropical climates. Invasive infections are limited to immunocompromised patients, particularly in those with prolonged neutropenia. The resulting fungemia can lead to subsequent dissemination of the lungs. It is not known how often the lungs are the primary site of disseminated *Trichosporon* infection, as pulmonary disease is not consistently seen in these cases. In one study of immunocompromised adults with disseminated trichosporonosis, 26.9% were found to have pulmonary involvement.[125] The typical clinical presentation in these cases included fever, dyspnea, cough, and hemoptysis. Renal involvement is also common and may initially manifest as microscopic hematuria or proteinuria. Disseminated *Trichosporon* infection is also associated with erythematous papules that can progress to bullae and necrotic lesions. Life-threatening disease can occasionally progress rapidly with hypotension, respiratory distress, and renal failure.[126]

## Imaging, Pulmonary Function Testing, Laboratory Findings

Chest radiographs in patients with pulmonary trichosporonosis infection typically show diffuse infiltrates with an alveolar pattern, although cavitary lesions and lobar consolidation have been described.

## Diagnosis

*Trichosporon* species grow well on standard fungal media, although differentiating *Trichosporon* spp. from *Candida* spp. can be difficult. The importance of distinguishing these two organisms is highlighted by the observation that *Trichosporon* spp. has shown decreased susceptibility to amphotericin B. Distinguishing between the various *Trichosporon* species is typically not performed in most clinical laboratories. Disseminated infection can be diagnosed when *Trichosporon* species is isolated from a sterile site such as blood, CSF or lung tissue. Skin biopsies can be helpful when skin lesions are associated with disseminated infection. Diagnosis can also be made by fungal culture from BAL fluid. Given that *Trichosporon* species can colonize mucosal surfaces, isolation from sputum and tracheal cultures should be interpreted based on the clinical context. Pseudoinfections due to inadequately sterilized bronchoscopes has also been reported.[127] Given that the genus *Trichosporon* is closely related to Cryptococcus, the *C. neoformans* polysaccharide antigen assay may be positive in patients with disseminated *Trichosporon* infection.[126]

## Management and Treatment

Patients with disseminated *Trichosporon* infection are typically severely immunocompromised. The degree of immunosuppression should be reduced if possible (e.g., GCSF administration, reducing glucocorticoids or other immunosuppressive medications). The azole class of antifungal drugs (particularly voriconazole) has good activity against *Trichosporon* spp., while significant resistance has been seen with amphotericin B based on in vitro susceptibility studies. The echinocandins are not active against *Trichosporon* spp.[128]

### Prognosis

Pulmonary infections due to disseminated trichosporonosis are associated with a high mortality rate. Patients who recover from their neutropenia have the best prognosis.[125]

## Hyalohyphomycosis (*Fusarium* spp., *Talaromyces* [Penicillium] *marneffei, Pseudallescheria boydii, Chrysosporium* spp.)

### Epidemiology and Etiology

Hyalohyphomycosis is caused by a heterogeneous group of filamentous molds that produce hyaline (translucent) hyphae on microscopic examination of clinical tissue specimens. These organisms are ubiquitous molds that are found in the soil and can occasionally cause disease in immunocompromised hosts.

*Fusarium* spp. (*F. solani, F. oxysporum,* and *F. moniliforme*) are a group of filamentous fungi that have long been known to cause infections of the nails, skin, and cornea of humans. These organisms have more recently been recognized as an infrequent but important cause of sinusitis, pulmonary disease, and disseminated infection in patients undergoing chemotherapy and HSCT. Corticosteroid therapy has also been found to be an important predisposing factor in developing fusariosis. The respiratory tract is the primary portal of entry for disseminated infection, although access through vascular catheters has also been reported.[129]

*Talaromyces* (formerly *Penicillium*) *marneffei* is a dimorphic fungus that has been identified as an important opportunistic infection in HIV-infected patients who live in or have traveled to eastern Asia.

The lungs are the likely portal of entry, as conidia from the environment convert to the yeast form prior to dissemination. Pulmonary alveolar macrophages are thought to be the primary pulmonary host defense[123] and impaired cell-mediated and alveolar phagocytic function are the main predisposing risk factors in AIDS patients. In more recent years, *T. marneffei* has been associated with non-HIV immunosuppressive conditions, including various autoimmune diseases, SOTs, HSCT, T lymphocyte–depleting immunosuppressive drugs, and anti-CD20 monoclonal antibodies.[130]

*Pseudallescheria boydii* and its asexual form, *Scedosporium apiospermum,* are fungi found in soil as well as polluted and stagnant water. In immunocompetent hosts, these organisms are an important cause of eumycetoma, a chronic granulomatous fungal disease of the subcutaneous tissues. Eumycetoma is rare in children and is typically seen in parts of Southeast Asia, Africa, and Central America. In immunocompromised hosts, disseminated disease can occur, with spread to the lungs or brain.

## Pathology/Pathogenesis

The pathogenesis of hyalohyphomycosis has not been well defined, as these organisms are minimally pathogenic in normal hosts.

## Clinical and Laboratory Features (Symptoms/Physical Findings)

The clinical features of hyalohyphomycosis are similar to those of IA, with sinus, pulmonary, cutaneous, and disseminated disease being seen. *Fusarium* spp. are best known as causes of sinusitis, pulmonary infections and fungemia. Chest imaging shows nonspecific alveolar or interstitial infiltrates, nodules, and cavities. Papular skin lesions with necrotic centers are common.[129]

Disseminated *T. marneffei* infection can present with the clinical syndrome of fever, lymphadenopathy, hepatosplenomegaly, pulmonary infiltrates, weight loss, and anemia. Patients with disseminated infection can also develop a papular rash with central necrosis that can initially be mistaken for molluscum contagiosum.[130] *T. marneffei* can mimic other infections such as tuberculosis, *Pneumocystis jirovecii* pneumonia, and cryptococcosis.

*P. boydii* (and its asexual form *S. apiospermum*) are causes of pulmonary disease in immunocompromised patients and are associated with a high mortality rate. Children with CGD are known to be at increased risk of pulmonary infection with *S. apiospermum*.[131] *P. boydii* has been reported to be an important cause of pneumonia in children with near-drowning events.[132]

### Diagnosis

*Fusarium* spp. is unusual in that it is the only mold that is commonly associated with fungemia. Fungal blood cultures are positive in 60%–82% of disseminated cases. Diagnosis can be made by isolation of the organism from culture of infected tissues.[56,133] The diagnosis of *T. marneffei* and *P. boydii* is typically made by histopathology or fungal culture of bone, bone marrow, or biopsy tissue from skin or lungs.[130]

The diagnosis of *P. boydii* (and *S. apiospermum*) is also made by culture and histopathologic examination of tissue. The septate hyphae of *P. boydii* can be indistinguishable from those of *Aspergillus* hyphae.

### Management and Treatment

Treatment for fusariosis includes amphotericin B or voriconazole. Combination antifungal therapy with amphotericin B or voriconazole showed no benefit when compared to those treated with monotherapy. Mortality from disseminated fusariosis has historically been greater than 50% despite antifungal therapy. Amphotericin B is the favored acute treatment of *T. marneffei* infection. After induction therapy, the patient can be transitioned to itraconazole as maintenance/suppressive therapy.[134] *P. boydii* and *S. apiospermum* can be resistant to amphotericin B but are typically susceptible to voriconazole, posaconazole and itraconazole.[133]

## Phaeohyphomycosis (*Bipolaris* spp., *Alternaria* spp., *Exophiala* spp., *Curvularia* spp., and *Scedosporium prolificans*)

## Epidemiology and Etiology

*Phaeohyphomycosis* refers to infections caused by a heterogeneous group of fungi (also known as the dematiaceous molds) that can occasionally cause invasive disease in immunocompromised hosts. More than 150 species have been identified as human pathogens, with the most important species causing invasive disease being *S. prolificans, Bipolaris* spp., *Alternaria* spp., *Exophiala* spp., and *Curvularia* spp.[135] The agents of phaeohyphomycosis are ubiquitous filamentous molds that are found in the soil and characterized by their darkly pigmented cell walls, which include melanin (the prefix *phaeo* is derived from Greek meaning "dark"). As with many molds that are responsible for invasive human disease, the respiratory tract is the usual portal of entry for these fungi. Extrapulmonary dissemination is known to occur in immunocompromised patients. This group of organisms is also known to contribute to allergy in humans, including asthma and allergic fungal sinusitis.[136] Various agents of phaeohyphomycosis (e.g., *S. prolificans, Exophiala* spp.) have been found to colonize the lungs of patients with cystic fibrosis, although it is unclear if these organisms play a role in the progression of this disease.[137]

## Clinical and Laboratory Features

Invasive infections are generally limited to immunocompromised hosts and localize to the sinuses, lungs, blood, CNS, skin and eyes. *Bipolaris* spp., *Exophiala* spp., *Curvularia* spp., and *S. prolificans* have been found to cause the majority of the cases of pneumonia and disseminated disease. The pulmonary manifestations of phaeohyphomycosis include lobar consolidation, asymptomatic solitary pulmonary nodules, and endobronchial lesions. *Bipolaris* spp. and *Curvularia* spp. are both known to cause fungal sinusitis.[136]

## Diagnosis

The primary method of diagnosis for all agents of phaeohyphomycosis is fungal culture and histopathologic examination of tissue. Microscopic examination is aided using Fontana-Masson stain, which will strongly stain the melanin within the conidia, spores, or hyphae. Even with proper staining, histopathologic interpretation can be difficult and may require referral to a mycology reference laboratory. No commercially available serologic, antigen or PCR assays are available for these organisms.[136]

## Management and Treatment

Therapy for invasive phaeohyphomycosis involves antifungal therapy and possible surgical resection of fungal lesions. In addition to diagnosis, isolation of the fungal pathogen allows for susceptibility testing to various antifungal agents. Amphotericin B has activity against many of the fungal organisms responsible for phaeohyphomycosis, although *S. prolificans* is usually resistant. Other antifungal agents with activity against certain organisms that cause phaeohyphomycosis include voriconazole, itraconazole, and posaconazole. Regardless of antifungal regimen, the mortality of disseminated invasive phaeohyphomycosis is greater than 70%.[136]

## Acknowledgments

The authors thank the following collaborators for their roles in obtaining radiographs and pathologic specimens used for the figures in this chapter: Richard M. Heller, Sharon M. Stein, and James D. Chappell. We also would like to thank Dennis O'Connor for his careful review of the manuscript.

## 32

# Pertussis and Other *Bordetella* Infections of the Respiratory Tract

*Ulrich Heininger MD*

Pertussis ("whooping cough") is an acute bacterial infection of the respiratory tract. The illness occurs worldwide and affects all age groups, but it is most serious in young, unprotected infants. It is caused by *Bordetella pertussis* (first described in 1906) and, less frequently, by *Bordetella parapertussis* (1937).[1–3] The term *pertussis* was coined in 1670 and means "violent cough." The clinical picture was described for the first time in 1640 by Guillaume de Baillou, based on a 1578 epidemic in Paris.[3]

## Epidemiology

Pertussis occurs worldwide, and humans are the only host of *B. pertussis*. Transmission occurs effectively by droplets, with secondary attack rates close to 100% in exposed susceptible individuals.[3] The incubation period is usually 7–10 days but may vary substantially. In a household contact study, secondary cases were noted to have their onset up to 6 weeks after the onset of illness in the primary case, especially when antibiotics were used.[4] Several studies have shown that females and males are equally affected by pertussis in childhood, whereas a female preponderance (55%–69%) is noted in adolescents and adults.[5–7] Most likely, this is due to more frequent contact of females with young children, from whom they acquire infection. The seasonal pattern of pertussis varies between different geographic locations.[6,7]

The epidemiology of pertussis caused by *B. pertussis* infection is incompletely understood. Reasons for this are the lack of a uniform case definition, inconsistent use of diagnostic laboratory tests, variable surveillance systems, and incomplete case ascertainment due to underconsulting, underrecognition, underdiagnosis, and underreporting.[8] Furthermore, epidemiology is greatly influenced by pertussis immunization programs that, with high coverage rates, confer not only individual protection but also herd protection to some extent. In contrast to *B. pertussis, B. parapertussis* infections appear to occur independent of immunization activities, and their relative frequency varies considerably by geography and time.[9,10]

Although in most countries pertussis still mainly affects infants and young children, it is increasingly diagnosed in adolescents and adults, who are also important sources of infection in young, unprotected infants in their families and households (Table 32.1).[11] In recent years, a shift from mothers to siblings as the predominant source of *B. pertussis* transmission to infants has been noted in the United States.[12] Among 1306 cases of pertussis in infants, the source of infection was identified in 569: overall, 35.5% were siblings, 20.6% were mothers, and 10.0% were fathers.

## Table 32.1

### Household Members as the Source of Pertussis in Infants

| Country | Investigator (Year) | Study Population | Observation[a] |
|---|---|---|---|
| United Kingdom | Crowcroft (2003)[64] | 25 infants <5 months of age admitted to ICU because of proven pertussis | Primary case:<br>Parent: $N = 11$ (44%)<br>Sibling: $N = 6$ (24%) |
| United States | Bisgard (2004)[65] | 616 infants with proven pertussis | Source discovered in 264 (43%) cases:<br>Parent: $N = 123$ (47%; 20% of total) |

| | | | |
|---|---|---|---|
| | | | Grandparent: $N = 22$ (8%; 4% of total)<br>Sibling: $N = 52$ (20%; 8% of total) |
| France | Bonmarin (2007)[66] | 1668 hospitalized infants <6 months of age with proven pertussis | Source discovered in 892 (53%) cases:<br>Parent: $N = 491$ (55%; 29% of total)<br>Sibling: $N = 223$ (25%; 13% of total) |
| Multinational | Kowalzik (2007)[67] | 99 infants admitted to ICU because of proven pertussis | ≥1 source ($N = 30$) discovered in 24 (24%) cases:<br>Parent: $N = 18$ (60%; 18% of total)<br>Other adult: $N = 6$ (20%; 6 % of total)<br>Sibling: $N = 5$ (17%; 5% of total) |
| Multinational | Wendelboe (2007)[68] | 95 infants <6 months of age admitted to hospital because of proven pertussis | ≥1 source discovered in 44 (46%) cases:<br>Parent: $N = 27$ (55%; ≈25% of total)<br>Grandparent: $N = 3$ (6%; ≈3% of total)<br>Sibling: $N = 8$ (16 %; ≈5% of total) |
| The Netherlands | de Greef (2010)[69] | 201 infants <6 months of age admitted to hospital because of proven pertussis | ≥1 source discovered in 96 (48%) cases:<br>Parent: $N = 53$ (55%; ≈25% of total)<br>Sibling: $N = 39$ (41%; ≈19% of total) |
| United States | Skoff et al. (2015)[12] | Cases of pertussis in infants, identified through "enhanced pertussis surveillance" in seven US states | Source identified in 569 (44%) cases: siblings (35.5%), mothers (20.6%), fathers (10.0%), grandparents (7.6%), aunts/uncles (6.5%), and other source, not specified (6.3%) |

[a] Restricted to household contacts; other sources, if any, were nonhousehold contacts.

*ICU*, Intensive care unit.

A resurgence of cases and a gradual shift toward an increase of pertussis in adolescents and adults has been noted in North America and elsewhere.[5] Whether this increase is caused by waning vaccine immunity and a decreased chance for natural boosters, a consequence of increased awareness and diagnostic tools or both is an ongoing debate. Of note, pertussis in adolescents and adults is frequently atypical, and true numbers of cases are certainly higher than reported.[5,13] Furthermore, in support of a true change in epidemiology, a rise in fatalities due to pertussis has been observed in infants in the United States during the last decades. Whereas 1.67 deaths per million infants per year were reported in the 1980s, the rate increased to an average of 2.40 in the 1990s. This increased incidence almost exclusively affected infants under 4 months of age.[14]

The crucial role that mass immunization plays in controlling pertussis has been clearly demonstrated in countries such as Japan, England, and Sweden, where infant pertussis vaccination was either discontinued or markedly curtailed as a result of unsubstantiated concerns about vaccine-related adverse events.[3]

## Etiology

*Bordetella* organisms are small, aerobic, gram-negative coccobacilli. Today, the genus comprises 10 different species, of which 9 have been shown to cause respiratory tract illness in humans; these species include *B. pertussis* and *B. parapertussis,* the causative agents of whooping cough; *B. bronchiseptica* and *B. holmesii,* which can cause variable respiratory symptoms; *B. trematum,* which has been found in ear and wound infections, and *B. petrii,* isolated from respiratory tract secretions in patients with cystic fibrosis and from a patient with mastoiditis.[1–3] However, the overwhelming majority of *Bordetella* infections are caused by *B. pertussis* and *B. parapertussis.*

## Pathology/Pathogenesis

The organism is transmitted by aerosol droplets from infected to susceptible humans. After transmission, adhesion of the bacteria to ciliated cells of the upper and lower respiratory tract establishes colonization, followed by multiplication and spread on the epithelium, local mucosal damage, and finally, induction of respiratory symptoms. Invasiveness is extremely rare.[15] Asymptomatic, transient colonization frequently occurs during reinfection in immune individuals.[16] Animal studies suggest that a variety of virulence factors is involved in the various steps of infection of the respiratory tract (Table 32.2). Expression of these factors is regulated in response to environmental changes by BvgAS, a two-component signal transduction system.[17] The precise mechanisms during *B. pertussis* and *B. parapertussis* infection in the human host are unknown. Laboratory studies suggest that several factors working in concert allow adherence of the organisms to the epithelium, and filamentous hemagglutinin (FHA) inhibits phagocytosis. Later on, effects caused by adenylate cyclase toxin and pertactin expression allow effective phagocytosis and killing of the bacteria by the host. The popular belief that pertussis is a single-toxin illness caused by pertussis toxin (PT), exclusively produced by *B. pertussis,* is refutable by the observation that a similar illness results from infection with *B. parapertussis,* which does not express PT.[10] Further insight into the pathogenesis of *Bordetella* infection will be gained now that several members of the genus have been sequenced.[18]

## Table 32.2

### Virulence Factors of *Bordetella Pertussis* and Their Specific Characteristics

| Factor (Gene) | BVG Regulation | Molecule | Major Role | Other Functions | Commen |
|---|---|---|---|---|---|
| Pertussis toxin (PTX) | Yes | "A" protomer and "B" subunits | Toxin and first-line adhesion factor | Causes leukocytosis by lymphocytosis | Precise r disease u |
| Filamentous hemagglutinin (FHA) | Yes | Large, filamentous protein (220 kDa) | Major adhesion; predominantly in trachea | Not known | Need for inclusion vaccine question |
| Fimbriae 2 and 3 (fim2, fim3, fimX) | Yes | Small, filamentous proteins (23 kDa) | Adhesion factor; predominantly in trachea | Agglutinogens; sustain infection | Importan stimulat host's im response |
| Pertactin (prn1, prn2, prn3) | Yes | 69-kDa outer membrane protein | Adhesion factor, induces type-specific antibody | Major protective antigen (mouse model) | Importan antigen, genotypi |
| Adenylate cyclase (cyaA) | Yes | Protein toxin | Toxin; inhibits phagocytosis by ↑ cAMP | Inhibits chemotaxis and induces apoptosis of macrophages | Candidat future va |
| Tracheal cytotoxin (TCT) | No | Peptidoglycan derivative | Toxin; paralyzes mucociliary clearance system | Inhibits DNA synthesis and cell death | Nonimm → not su vaccine |
| Dermonecrotic toxin (DNT) | Yes | Heat-labile toxin (140 kDa) | Toxin; dermal necrosis and vasoconstriction | Effect only after injection in skin | Role in h disease u |
| Tracheal colonization (tcfA) | Yes | Proline-rich protein | Adhesion factor; predominantly in trachea | Not known | C-termin homolog factor br vag-8 |
| *Bordetella* resistance to killing factor (brkA) | Yes | Outer membrane protein (32 kDa) | Adhesion factor | Provides resistance to complement | C-termin homolog tcfA, and |
| Virulence-activated gene 8 (vag-8) | Yes | Outer membrane | Adhesion factor (?) | Not known | C-termin homolog |

| | | | | | |
|---|---|---|---|---|---|
| | | protein (95 kDa) | | | tcfA, and |
| Lipooligosaccharide (wlb) | Yes | Lipid A and trisaccharide | Presumably required for nasal colonization | Not known | Substanti species-s structure *Bordetella* |
| BVG intermediate-phase (bipA) | Yes | Outer membrane protein (137 KDa) | Transmission (?) and adhesion factor | Not known | First of a class of *B* protein A antigens (“interme phase”) |
| Type III secretion system (bsc) | Yes | Several, not yet specified proteins | Secretes effector proteins into host cells | Downregulation of the host immune system | Appears functiona *B. bronchi* (and som *parapertu* strains) |
| bteA (bteA) | Yes | Linked to type III secretion system (72 kDa) | Induction of cytotoxicity | Persistent infection (animal model) | Potential antigen |

*BVG*, *Bordetella* virulence gene; *CAMP*, cyclic adenosine monophosphate; *wlb*, *Bordetella pertussis* lipopolysaccharide biosynthesis locus (formerly Bpl).

Modified and updated from Heininger U. Recent progress in clinical and basic pertussis research. *Eur J Pediatr*. 2001;160:203-213.

The pathology of pertussis has been characterized by studies of *B. pertussis* infection. It causes inflammation, congestion, and infiltration of the respiratory mucosa with lymphocytes and granulocytes and leads to accumulation of viscous secretions in the lumens of the bronchi, bronchiolar obstruction, and occasional atelectasis.[3] Later in the infection, necrosis of the midzonal and basilar parts of the bronchial epithelium result in necrotizing bronchitis (Fig. 32.1). Subsequently, bronchopneumonia may develop, either caused by *B. pertussis* itself or by secondary infections with other pathogenic bacteria.

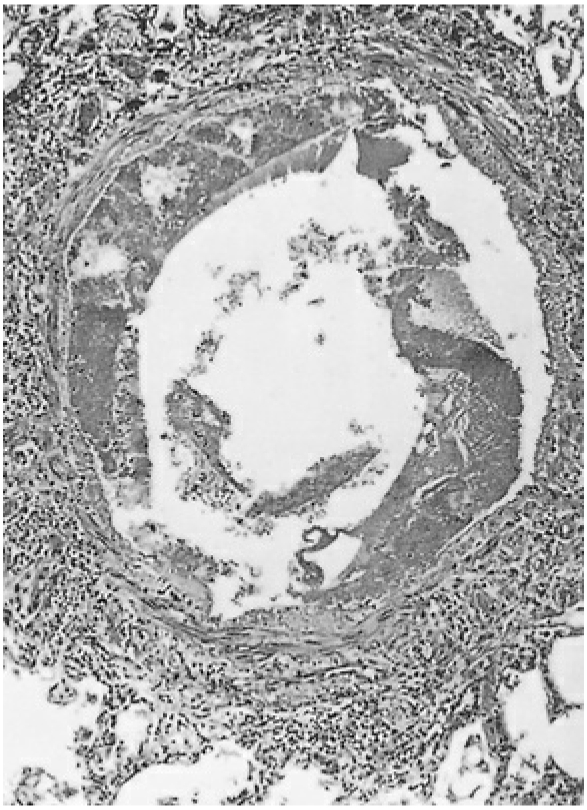

**FIG. 32.1** Necrotizing bronchitis (×100).

Infection with *B. pertussis* of a previously naive host results in the production of serum and salivary antibodies against a number of antigens such as PT, FHA, pertactin, and adenylate cyclase toxin.[19–21] Enzyme-linked immunosorbent assay techniques allow discrimination of class-specific antibodies, with Immunoglobuline G (IgG) being more reliably detectable than Immunoglobulines A, E, and M. In individuals who have been "primed" by *B. pertussis* infection or immunization, reinfection will elicit a secondary immune response with or without concomitant symptoms.[16] Of note, infection with *B. pertussis* does not provide lifelong immunity, and apparently no cross protection exists between different species of *Bordetella.*[11,22] After natural infection, sustained IgG and IgA serum antibody levels against FHA, pertactin, and—though less—PT have been observed before returning close to baseline values after approximately 5 years.[23,24] Yet the precise role of serum antibodies in immunity against pertussis is a matter of ongoing debate, and various studies show conflicting results.[25,26]

Cell-mediated immune responses to *B. pertussis* have been shown to play an important role in protection against pertussis. In mice, challenge with *B. pertussis* resulted in a predominant T helper 1

(Th1) cell–mediated immune response followed by complete bacterial clearance.[27] Specific protection could be conferred by adoptive transfer of immune spleen cells into immunosuppressed mice, further underlining the role of Th1 cells. Interestingly, persistent vaccine efficacy has been documented in young children several years after immunization despite significant antibody decline, and it was also preferentially mediated by Th1 cells.[28]

# Clinical Features

## Symptoms

Typical pertussis is a three-stage illness, comprising catarrhal, paroxysmal, and convalescent phases.[3] The catarrhal stage lasts for about 1–2 weeks and is characterized by flulike symptoms such as coryza, sneezing, lacrimation, conjunctival injection, malaise, and nonspecific cough. It is followed by the paroxysmal stage, which in classical cases is marked by an increase of frequency and severity of coughing, with paroxysms as the most typical feature; characteristically, repetitive series of 5–10 or more hacking spells of cough occur during a single expiration. At the end of a paroxysm, a typical whoop, which is caused by the sudden rush of inspired air through a narrowed glottis, is noted. Paroxysms may occur up to several times per hour, during both day and night, triggered by various stimuli such as eating and drinking and physical or emotional stress. The paroxysmal stage may last from a few days to several weeks, until the convalescent stage is reached; this phase is marked by a decrease in the frequency and severity of coughing spells. However, over a period of several months, similar coughing episodes may again occur, often associated with other respiratory tract infections. Notably, *B. pertussis* infections present with considerable variability, which primarily depends on age, previous immunization, or infection. Other variables—including the presence of passively acquired antibody (in young infants), degree of exposure to the source of infection, specific bacterial inoculum, host genetic and acquired factors, and genotype of the organism—may contribute to attenuation of symptoms.

The variability of symptoms is exemplified by results from a study of 1860 culture-positive cases in unvaccinated children and adolescents in Germany. In that study, 38% of patients had a total coughing illness duration of 4 weeks or less, 18% had nonparoxysmal cough, 21% did not whoop, and 47% did not have posttussive vomiting.[7] On rare occasions, *B. pertussis* infection has been found to cause otitis media and to be associated with unilateral hyperlucent lung (MacLeod or Swyer-James syndrome) and the hemolytic uremic syndrome.[29–31]

Overall symptoms with *B. parapertussis* infection are similar to those caused by *B. pertussis,* but illness is usually less severe and of shorter duration.[10] Dual infections of *B. pertussis* and *B. parapertussis* have been observed.[32] Occasionally *B. bronchiseptica* and *B. holmesii* have been isolated from children with pertussis-like illness.[33,34] The clinical role of *Bordetella* species isolated from sputum specimens in patients with cystic fibrosis is currently unknown.[35]

## Physical Findings

Cyanosis, neck vein distention, bulging eyes, tongue protrusion, salivation, lacrimation, sweating, and posttussive vomiting of food or viscous mucus may occur with pertussis. Fever is usually minimal or absent. There is a wide spectrum of complications of pertussis, most of which predominantly occur in young infants (Table 32.3). Respiratory complications include bronchopneumonia with or without atelectasis, pulmonary hypertension, and otitis media mainly secondary to other respiratory tract pathogens. Pertussis has also been associated with activation of latent tuberculosis. Additional complications that have been observed as a consequence of pertussis include ulcer of the frenulum of the tongue, epistaxis, melena, subconjunctival hemorrhages, meningoencephalitis, encephalopathy with cerebral seizures, tetanic seizures caused by severe alkalosis as a result of loss of gastric contents due to persistent vomiting, subdural hematomas, spinal epidural hematoma, rupture of the diaphragm, rib fracture, umbilical hernia, inguinal hernia, rectal prolapse, dehydration, syndrome of inappropriate antidiuretic hormone secretion, apnea, and nutritional disturbances.[3] Death secondary to pneumonia, pulmonary hypertension, or sudden death, probably due to severe hypoxemia, occurs mainly in infants, for whom the mortality rate is 0.6%.[6,36]

## Table 32.3

### Complications in 1640 Unvaccinated Patients With *Bordetella Pertussis* Infections by Age Group as Reported in Follow-Up Questionnaires

| **Complication** | **AGE** | | | | | |

[a] Includes cases of epistaxis, inguinal hernia, frequent paroxysms, and bronchitis.

From Heininger U, Klich K, Stehr K, Cherry JD. Clinical findings in Bordetella pertussis infections. Results of a prospective multicenter surveillance study. *Pediatrics*. 1997;100:e10.

# Imaging, Pulmonary Function Testing, Laboratory Findings

Uncomplicated pertussis does not require any imaging studies. The role of radiographic imaging in pertussis is limited. The most frequent abnormalities are consolidation, atelectasis, and hilar lymphadenopathy. In a case series of 238 hospitalized patients with pertussis, radiographic abnormalities were detected in 63 patients (26%). Pulmonary consolidation was seen in 50 patients (21%), atelectasis in 9 (4%), and lymphadenopathy in 22 (9%). Most consolidations were peribronchial (72%). For unknown reasons, both atelectasis and consolidation were more common on the right and predominantly involved the lower and middle lobes of the lung. Radiographic abnormalities were more common beyond infancy. Follow-up radiographs after 1 month demonstrated no significant radiographic sequelae.[37] One can conclude that chest radiographs should be limited to severe cases and when pulmonary complications are suspected on the basis of clinical findings.

Most cases of pertussis caused by primary *B. pertussis* infection in unvaccinated individuals will demonstrate leukocytosis due to lymphocytosis. This is caused by the effects of PT, which appears to reduce L-selectin expression by the T cells and thus prevents their homing to the lymphoid tissues.[38] Hyperleukocytosis (>30,000/mm$^3$) correlates with severity of pertussis in young infants. In a case series of 31 infants 3 months of age or less with pertussis severe enough to require intensive care, those with pulmonary hypertension or who died had higher leukocyte counts (>30,000/mm$^3$) and were more likely to have tachycardia, tachypnea, and pneumonia than those who did not have pulmonary hypertension or survived.[39]

In contrast, secondary infections and breakthrough cases of pertussis in vaccinated patients (with preexisting IgG antibodies to PT) usually lack leukocytosis, as do patients infected with *B. parapertussis* (which does not express PT).[10]

# Diagnosis and Differential Diagnosis

In typical cases, a diagnosis of pertussis can be established on the basis of characteristic symptoms. Isolation of *B. pertussis* or *B. parapertussis* from a person with a cough illness provides certainty of the diagnosis. Nasopharyngeal specimens (NPSs), obtained by aspiration, calcium alginate or Dacron swabs, and specific media (Regan-Lowe or Bordet-Gengou agar and modified Stainer-Scholte broth) are necessary to recover *Bordetella* species. Direct fluorescent antibody staining is no longer recommended due to lack of sensitivity and specificity. Sensitivity of culture is optimal (≈95%) in unvaccinated, untreated individuals early in the course of the illness, when clinical suspicion of pertussis is usually low. During the paroxysmal phase, sensitivity of culture rapidly declines to 50% or lower. Over the last two decades, the polymerase chain reaction

(PCR) technique applied to NPSs has markedly improved the diagnosis of pertussis. Recently a combination of induced sputum and NPS has been shown to increase the diagnostic yield of *B. pertussis* by PCR considerably (i.e., from 17 [NPS only] to 32 [NPS plus induced sputum] positive results in 460 South African children hospitalized for lower respiratory tract infections).[40] PCR is particularly useful in oligosymptomatic cases, in patients who have been started on antibiotics (where PCR may remain positive for prolonged periods of time) and in patients with progressed illness.[41] In addition, the sensitivity of PCR in general is higher than that of bacterial culture; PCR is therefore the preferred diagnostic tool. Advanced technology today allows discrimination between different species of the *Bordetella* genus, and recent developments such as real-time detection of the amplification products and LightCycler PCR now provide results within a few hours.[42,43]

Serologic tests are the most sensitive technique for the diagnosis of *Bordetella* infections. Enzyme immunoassays have been most widely applied, and although whole-cell preparations of *B. pertussis* can be used as antigens, purified proteins such as PT, FHA, and pertactin are preferable for their better specificity. IgG antibody assays provide sufficient sensitivity, but the addition of IgA assays may be helpful. Although paired acute- and convalescent-phase serum samples are optimal, analysis of a single serum specimen is more appropriate for routine purposes. Unfortunately, however, serology tests are not standardized and interpretation of results is difficult in the presence of vaccine-induced preexisting antibodies.[44] Therefore test results have to be interpreted cautiously, and cutoff values derived from age-matched control groups are required. IgA antibodies have traditionally been considered to be reliable indicators of recent or acute infection. A recent study, however, has shown persistently high IgA antibodies against both FHA and pertactin and, though less pronounced, also against PT for as long as 30 months after infection.[24] This observation further complicates the serologic diagnosis of *B. pertussis* infection in single-serum analyses.

Several microorganisms other than *B. pertussis* or *B. parapertussis* can cause cough illnesses that can occasionally be confused with pertussis. In one study from Germany, the frequency of serologic evidence for an infection with microorganisms other than *B. pertussis* was assessed in children with pertussis-like illnesses.[45] Of 149 such children, a diagnosis of adenovirus ($n = 33$); parainfluenza viruses 1, 2, and 3 ($n = 18$); *Mycoplasma pneumoniae* infection ($n = 15$); and respiratory syncytial virus infection ($n = 14$) was made. In studies of concurrent outbreaks of *Mycoplasma* and *B. pertussis* infections, it has been shown that clinical symptoms alone lacked adequate specificity to distinguish pertussis from mycoplasma infection.[46] Moreover, in populations with high immunization rates, atypical presentations of *B. pertussis* may be more frequent than classical illness, and a high index of clinical suspicion is imperative in the diagnosis of pertussis.[7] These observations underscore the need for appropriate laboratory tests if there is any doubt about the diagnosis.

## Management and Treatment

Several antibiotics have proven in vitro activity against *B. pertussis* and *B. parapertussis.*[1] Sufficient minimal inhibitory concentrations have been demonstrated for macrolides and for fluoroquinolones. In contrast, minimal inhibitory concentrations of oral beta-lactam antibiotics, including cephalosporins, are unacceptable and render them unsuitable for the treatment of pertussis. Oral erythromycin (succinate formulation at 50 mg/kg body weight per day given every 6–8 hours or estolate formulation at doses of 40 mg/kg per day at 12-hour intervals for 14 days) is still the preferred treatment in neonates and young infants. When given in the catarrhal or early paroxysmal stage of the illness, this will ameliorate the symptoms, eradicate the bacteria from the nasopharynx within a few days, and terminate contagiousness of the patient. Of the different formulations, erythromycin is favored by most experts. Erythromycin remains the first-line drug, although resistance has been observed in single isolates and ongoing surveillance of antibiotic susceptibility is a challenge in the era of PCR diagnostics.[47] The mechanism underlying resistance is currently unknown. Seven days of treatment with erythromycin estolate was shown to be as effective as 14 days of treatment in a large Canadian study.[48] It should be noted, however, that this investigation was carried out in a highly vaccinated community, and results may have been different in unvaccinated children.

Macrolide antibiotics with improved gastrointestinal tolerability, such as clarithromycin or azithromycin, demonstrate efficiency comparable to that of erythromycin and are preferred in older children and adolescents.[49] In Canada, the microbiologic and clinical efficacy and the clinical safety of a 7-day course of clarithromycin (15 mg/kg per day in two doses for 7 days) was compared with a 14-day course of erythromycin (40 mg/kg per day in three doses for 14 days) in a prospective, randomized, single-blind (investigator) trial in children from 1 month to 16 years of age with culture-proven pertussis.[50] Nasopharyngeal cultures for *B. pertussis* were performed at enrollment and the end of treatment. Microbiologic eradication and clinical cure rates were equal: 100% (31/31) for clarithromycin and 96% (22/23) for erythromycin. Patients on clarithromycin had significantly fewer adverse events (45%) than those on erythromycin (62%).

In an open, uncontrolled study in the United States, 34 subjects (most of them children) with culture or PCR-proven *B. pertussis* infection received a 5-day course of azithromycin (10 mg/kg in a single dose on the first day and 5 mg/kg per day as single doses on the following 4 days). *B. pertussis* was eradicated from the nasopharynx in 33 (97%) of 34 patients after 72 hours, and all were negative on follow-up after 2–3 weeks.[51] Azithromycin is also the preferred antibiotic in neonates.[3] It is noteworthy that when azithromycin or erythromycin is used in young infants (<6 weeks, particularly <2 weeks of age), the increased risk for hypertrophic pyloric stenosis should be borne in mind, and parents need to be educated about the symptoms of this disease.[52]

Young infants, who are threatened by hyperleukocytosis and hypoxemia associated with apneic spells, should be hospitalized and their blood oxygen saturation closely monitored. Careful removal of respiratory secretions and oxygen supplementation may be necessary. Uncontrolled observations indicate that corticosteroids and/or β-adrenergic drugs adjunctive to antibiotics may ameliorate respiratory distress associated with pertussis, but evidence of efficacy is lacking.[3] Pneumonia, frequent apneic spells, and significant respiratory distress may require assisted ventilation, especially in neonates and young infants.[3] In young infants, extreme leukocytosis (>50,000/μL) and pulmonary hypertension carry a high risk for respiratory and cardiovascular failure. In spite of intensive treatment efforts—such as pulmonary artery vasodilators, exchange transfusion to reduce leukocytosis, and extracorporeal membrane oxygenation—the outcome of these complicated courses is frequently fatal.[53,54]

General supportive medical treatment is important for patients with pertussis. Physical and emotional stress, which may trigger paroxysms, should be avoided. Furthermore, if posttussive vomiting is present, careful attention should be paid to adequate fluid and food intake. Respiratory isolation precautions should be implemented until 5 days of effective antibiotic treatment have been received. There is no role for intravenous antipertussis immunoglobulin treatment and no such products are commercially available.

# Prevention

Prevention of pertussis is possible by avoidance of exposure, postexposure antibiotic treatment, and immunization. Avoidance of exposure is usually impossible in clinical practice, given that contagiousness is highest during the early stage of illness in the primary case where commonly a diagnosis of pertussis has not yet been made. Prophylactic use of erythromycin (or clarithromycin or azithromycin) has been shown to protect from *B. pertussis* infection when given to close contacts and is most useful when administered before the occurrence of the first secondary case.[55] Recommended antibiotic dosage and duration is the same as for treatment and should be given to all close contacts regardless of age and immunization status according to recommendations by the American Academy of Pediatrics.[56] Postexposure active immunization should also be considered in unimmunized or incompletely immunized individuals by use of a dose of age-appropriate pertussis vaccine.

Active immunization is the most effective way to prevent pertussis. Over the last decades, acellular pertussis vaccines (containing various numbers and quantities of *B. pertussis* antigens) have been developed and studied for safety, immunogenicity, and efficacy; these have been implemented in most countries worldwide.[1] Virtually all countries recommend a primary series of two or three vaccine doses in infancy and usually also a reinforcing dose in the second year of life. Timely initiation of the immunization series, usually at 6 weeks to 2 months of age, is crucial, because the risk of severe pertussis in immunized infants decreases from dose to dose as compared with the risk in unimmunized infants.[57] The optimal timing and number of further booster immunizations is a matter of ongoing debate.[8] Because vaccine-induced efficacy is sustained despite declining antibody values, observational studies are needed to answer these questions. Investigations conducted so far indicate ongoing efficacy for several years after three or four doses of acellular pertussis vaccine.[1] Today most countries recommend booster doses at preschool age and/or in adolescents. Furthermore, several countries—including the United States, Canada, France, and Germany—have introduced a universal pertussis booster dose in adults regardless of age.[58]

Overall, when compared with conventional whole-cell pertussis vaccines, acellular component vaccines have been shown to cause lower rates of local and systemic reactions such as fever.[3] Also, severe reactions such as febrile seizures and hypotonic-hyporesponsive episodes declined significantly (79% and 60%, respectively) with the broad dissemination of acellular pertussis vaccines.[59] Of some concern is that local reactions after pertussis immunization increase from dose to dose, and whole-limb swelling at the site of injection may occur. Yet these side effects are only temporary, usually do not interfere with the child's well-being, and are without known sequelae. Furthermore, they are considered to be less severe than those seen after five consecutive doses of whole-cell vaccine.[60] Providing timely and complete immunizations against pertussis for all infants and young children, followed by regular booster doses as needed throughout life, will be crucial to better control of pertussis in the future.

A new concept that holds promise in protecting young infants from death by pertussis is that of immunizing women during pregnancy, ideally around 28–32 weeks of gestation.[61,62] Hence maternal IgG antibodies against PT will be boosted and transferred to the fetus via the placenta, so that they will persist at comparatively high levels throughout the first weeks of life. When a young infant is then infected with *B. pertussis*, this passive immunity is then thought to reduce the risk for hyperleukocytosis, the major risk factor for fatal disease. This mechanism is assumed to be the basis for the protective effect provided to infants by maternal immunization.

## Prognosis

There is no evidence for long-term sequelae such as allergic sensitization after pertussis.[63]

## Toxocariasis

Toxocariasis is a soil-transmitted zoonotic roundworm infection transmitted to humans by contact with canine and feline feces. It causes two main diseases in humans: visceral toxocariasis (VT), formerly known as visceral larva migrans, and ocular toxocariasis (OT), formerly known as ocular larva migrans.[1] VT results from an inflammatory response to the migration of immature, second-stage larvae through the viscera of a host that is not suitable for completion of the parasite's life cycle. The lung parenchyma is commonly involved in this form of the disease.

## Epidemiology

*Toxocara* species are found worldwide in domesticated and wild dogs and cats. Infection with *Toxocara* spp. is more prevalent than realized, because many individuals do not express the complete VT syndrome. Current seroprevalence data place toxocariasis among the most common zoonotic infections worldwide.[2] The global prevalence of *Toxocara* spp. in humans varies widely and is dependent upon factors such as population density, sanitation, poverty, education, and enforcement of laws regarding proper disposal of animal excreta.[1,2]

Toxocariasis is also endemic throughout the United States.[3] In one seroprevalence study conducted more than 20 years ago by the Centers for Disease Control and Prevention (CDC), using a nationally represented set of banked sera from the First National Health and Nutrition Examination Survey (NHANES 1971–1973), the seroprevalence of *Toxocara* antibodies, as measured by enzyme-linked immunosorbent assay (ELISA), varied from 4.6% to 7.3%.[4] However, rates approaching 30% were seen among black children of lower socioeconomic status.[4] A second seroprevalence study, also conducted by the CDC (NHANES 1988–1994), found an overall prevalence of 13.9%.[3] As in the prior survey, rates varied between different geographic regions and were influenced by socioeconomic conditions.[5] Similarly, seroprevalence rates also vary in other industrialized countries, particularly those that are resource rich versus resource poor, with higher rates seen in rural or underserved areas with high rates of poverty, overcrowding, and poor hygiene.[2,6,7]

Infection in the definitive host may be through multiple routes including vertical, transplacental (not in cats), and transmammary, as well as horizontal. The ability to survive and develop to sexual maturity in the intestinal tract of several vertebrate species has contributed to the worldwide propagation of the species. Puppies are especially dangerous, because transplacental infection results in 77%–100% of puppies becoming infected, and many pups are born with congenital canine toxocariasis.[6,8] They can then shed millions of eggs into the environment depending on the immune status of the host as well as the intensity of the *Toxocara canis* infection. By the time the animals are 3 weeks old, mature egg-laying worms can be present. Adult female worms can produce and shed more than 200,000 ova per day, which are then passed unembryonated onto the soil in the feces of the infected animal. Under suitable soil conditions (temperature 10–30°C, availability of light, suitable pH and humidity), the ova become embryonated and infectious after a minimum of 2–3 weeks. Because of the thick shell, the embryonated ova can survive in moist soil for months or even a few years. Most infections in children affect those with a history of pica or individuals who have accidentally ingested contaminated soil. Children also become infected commonly while playing in backyards, parks, playgrounds, and sandboxes where it is easy to come in contact with infectious ova.[2,9]

## Etiology

Two species of the genus *Toxocara* are primarily responsible for most cases of VT: dogs, wolves, coyotes, and foxes are the definitive hosts for *T. canis,* whereas domestic cats are the host for *T. cati.* Other *Toxocara* spp. have been implicated in human infection, including *T. vulpis (canine whipworm) and T. vitulorum (found in cattle).* The role of *T. lyncus* (wild cats) and *T. malaysiensis* (domestic cats) in causing human infection is not clear. In addition, *Baylisascaris procyonis (raccoon roundworm), Capillaria hepatica (rodent nematode), Ascaris suum (pig roundworm),* and rarely *Ascaris lumbricoides,* hookworm larvae, as well as *Strongyloides stercoralis* can cause a VT-like syndrome.[2,10]

## Pathology/Pathogenesis

In the natural host, infectious ova are ingested and hatch in the upper alimentary tract. The second-stage larvae then migrate through the intestinal walls into the bloodstream and then into the liver and lungs of the infected animal. From the lungs, the larvae mature by migrating through the tracheobronchial tree and passing into the upper alimentary tract. There, the mature worm can begin laying eggs, which pass out in the feces to begin the cycle anew.

In aberrant hosts, such as humans, the initial stages of infection are identical: infectious second-stage larvae hatch in the small intestine and then begin migrating through blood and lymphatics to the liver, lung, brain, and other organs such as the eye. Before the larvae can complete their transtracheal passage and maturation to adult worms, however, host defenses block further migration of the larvae by encasing them within a granulomatous reaction, which is generally eosinophilic in nature. The pathogenesis of VT is the direct result of the immunologic response of the body to the dead and dying larvae. Multiple eosinophilic abscesses may develop in the infected tissues. The larvae remain alive and infective for an indefinite period of time, often as long as 7 years. The inflammation appears as an eosinophilic granuloma, and an open biopsy of a granulomatous lesion will often show the *Toxocara* larva. Host antibodies are generated against the *Toxocara* excretory-secretory (TES) antigens of the larvae. These glycoprotein antigens contain protease, acetylcholinesterase, and eosinophil-stimulating activity. They also elicit Th 2 immune responses and high levels of interleukins 4 and 5.[11]

## Clinical Features

### Symptoms

It is the immediate hypersensitivity response to the larvae that manifests as symptoms of VT. The specific signs and symptoms depend on the organ affected. *Toxocara* is mainly an infection of young children, since they have a greater opportunity to ingest the infectious ova. The classic case occurs in a male child, younger than 6 years, with a history of pica and exposure to dogs. A child with fever of unknown etiology and eosinophilia with the appropriate epidemiological history should be assumed to have *Toxocara* infection until proven otherwise. The extent of signs and symptoms depends on the number and location of granulomatous lesions and the host's immune response.

Pulmonary toxocariasis is generally asymptomatic or may present with symptoms such as mild cough and dyspnea.[12] The initial symptoms may include a prodrome of anorexia, fever, and malaise. The so-called “covert toxocariasis” has been implicated as responsible for many subtle clinical manifestations. In a study of children in Ireland, a plethora of clinical manifestations were seen including fever, headache, anorexia, abdominal pain, nausea, vomiting, lethargy, sleep and behavior disorders, pharyngitis, pneumonia, cough, history of wheezing, limb pain, cervical lymphadenitis, and hepatomegaly.[13,14] Another case-control study in French adults led to the term "common toxocariasis," a syndrome comprising chronic dyspnea and weakness; cutaneous rash; pruritus and abdominal pain, often with eosinophilia; elevated levels of immunoglobulin E (IgE); and high titers of *Toxocara*-specific antibodies.[15] Both "covert" and "common" toxocariasis probably represent variations in the clinical spectrum of mild *Toxocara* childhood and adult disease.

The time course for VT may be quite prolonged. The initial stage of the illness lasts several weeks, beginning with low-grade fevers and nonspecific symptoms and progressing to eosinophilia and hepatomegaly. Episodes of bronchitis, asthma, or pneumonia may occur. Over the next month, intermittent high fevers occur along with the major manifestations of the disease. Recovery may take as long as 1–2 years, during which time the eosinophilia resolves along with the hepatomegaly. Resolution of pulmonary infiltrates occurs more rapidly.

With more severe involvement, various combinations of abdominal pain, arthralgias, myalgias, weight loss, high intermittent fevers, and neurologic disturbance may be seen. Acute respiratory failure has been reported from *Toxocara* infection.[16]

Other symptoms can include idiopathic seizure disorder, functional intestinal disorders, skin diseases (prurigo and chronic urticaria), eosinophilic and reactive arthritis, and angioedema.

## Physical Findings

These depend on the extent of the infection, the organ system involved, and whether the disease is systemic or limited to a specific organ. The lung is one of the most common organs affected in children with toxocariasis. Cough, if present, is generally nonproductive. Wheezing is the most frequent finding on chest examination, although rhonchi and crackles also have been described.[17] Because of the wheezing, some patients are diagnosed initially as suffering from asthma. Multiple studies have looked at the relationship between the seroprevalence of *Toxocara* infection and asthma and found that there is a significant positive correlation. In fact, toxocariasis is a well-recognized environmental risk factor for asthma in endemic regions.[18] Apart from pulmonary involvement as noted previously, other symptoms in VT depend on organ involved; hepatomegaly of varying degrees is almost always present.

## Imaging, Pulmonary Function Tests (PFTs), Laboratory Findings

There is no typical chest radiographic finding. Multiple pulmonary infiltrates or nodules may be seen; however, these are not pathognomonic.[19,20] A recent study reported that all nodules seen in children with *Toxocara* infection on computed tomography (CT) scan, whether they were single or multiple, were in the peripheral area of the lungs. Less commonly pleural effusion has also been reported in association with the infection.[21] Descriptions of imaging studies range from patchy airspace disease with pseudonodular infiltrates on CT scan to diffuse interstitial pneumonitis to an asymptomatic pulmonary mass. The latter may at times raise the suspicion for malignancy on initial evaluation.[22,23] As with other eosinophilic pneumonias, pulmonary involvement in toxocariasis may present as patchy ground-glass opacities on initial CT scan findings. A recent study reported the presence of focal linear opacities on CT scan.[24] A pattern similar to miliary tuberculosis (TB) has also been reported in severe cases. The varied radiologic patterns may reflect whether direct larval invasion of lung tissue or a hypersensitivity reaction to larval antigens is the primary pathologic process present in that particular patient.

Pulmonary function testing may reveal diminished lung function with decreased forced expiratory volumes in one second (FEV1).[25] Bronchiectasis may result from chronic lung infection.[26]

Neutrophilia occurs during the first few days but rapidly gives way to the eosinophilia classically seen in the disease. Eosinophilia can range up to 50%–90% of the total white blood cell count. Leukocytosis is generally present, with extreme values of over 100,000 cells/mm$^3$ occasionally reported.[27]

Other laboratory findings also may be helpful in supporting a diagnosis of VT. Serum IgE levels are above 900 UI/mL in 60% of patients tested. Hypergammaglobulinemia is frequently reported and characterized by elevations of any one or all of the immunoglobulin classes.[28,29] Because of cross-reactivity between larval and blood group antigens, many patients will develop high anti-A and anti-B isohemagglutinin titers that persist for months after the initial infection.[29] Bronchoalveolar lavage fluid also may exhibit a relative eosinophilia.

## Diagnosis and Differential Diagnosis

ELISA and Western blot (WB) using the larval TES antigens to detect the host's antibodies are the most widely available and accepted tests for confirmation.[30] If a titer above 1 : 32 is considered, the diagnostic sensitivity is approximately 78% with a specificity of over 92%.[31] Because antibodies against *Toxocara* are present for years, an antigen-capture ELISA has been developed to separate acute from dormant infection.[32] Most recently, polymerase chain reaction (PCR) tests and recombinant antigen based assays on the Luminex platform, have also been developed.[33] The latter perform similarly to the existing TES-antigen WB and better than the TES-antigen ELISA method. However, they may not be widely available in underresourced countries where there is a high burden of disease.

Examination of the stool for ova and parasites is not helpful because the larvae rarely mature in humans. Before the ELISA against TES antibodies was developed, tissue biopsy to demonstrate the larvae in eosinophilic granulomas was the definitive test for diagnosis. Skin tests, other serologic testing, and fluorescent antibody techniques were troubled by low sensitivities and unacceptably high cross-reactivity with other parasitic infections.

Differential diagnosis should include the visceral lesions that may be produced by other nematode worms, as well as immature stages of certain nematodes and filarial worms. Invasion of the liver by *Fasciola hepatica,* a nematode worm, or *Capillaria hepatica,* a trematode, might be included. Also to be considered in this diagnosis are trichinosis, hepatitis, leukemia, other causes of intense eosinophilia, TB, asthma, lead poisoning, and the leukemoid reaction occurring in severe bacterial pneumonia.

## Management and Treatment

Treatment depends on the severity and location of the infection. Albendazole or mebendazole are the treatments of choice for *Toxocara* infections, although albendazole is not approved by the Food and Drug Administration (FDA), for this particular indication, and mebendazole is no longer available in the United States (Table 33.1). Thiabendazole and ivermectin have also been used. Most patients recover without any specific anthelmintic therapy. Corticosteroids along with antihelminthic treatment have been useful in patients with severe pulmonary and ocular involvement, possibly by also treating the hypersensitivity component of the disease as well.[34] Surgery may be indicated in some cases with ocular disease. Otherwise, treatment is symptomatic.

### Table 33.1

**Recommended Treatment Options: Toxocariasis, Echinococcosis, Strongylodiasis, Paragonimiasis[e]**

| Disease | Drug | Dose and Duration |
|---|---|---|
| Toxocariasis | Albendazole | 400 mg by mouth twice a day for 5 days (adult & child) |
| | Mebendazole | 100–200 mg by mouth twice a day for 5 days (adult & child) |
| Echinococcosis | Albendazole | Adults: 400 mg by mouth twice a day for 1–6 months<br>Children: 10–15 mg/kg/day (max 800 mg) by mouth twice a day for 1–6 months |
| | Mebendazole | 50–60 mg/kg/day in three divided doses for 3–6 months up to 1 year[a] |
| Strongyloides | Ivermectin[b] | 200 µg/kg given as a single dose for 1–2 days |
| | Albendazole | 400 mg by mouth 2 times daily for 7 days |
| Paragonimus | Praziquantel | 25 mg/kg given orally three times a day for 2 days[c] |
| | Triclabendazole[d] | 10 mg/kg once or twice |

[a] 100–200 mg/kg/day for 3 months has also been used successfully in children without any serious complications reported.

[b] Oral Ivermectin is available for human use in the United States. Relative contraindications for the use of ivermectin include: pregnant women, confirmed or suspected *Loa loa* infection, and those weighing less than 15 kg. For Strongyloides associated hyperinfection syndrome, Ivermectin should be given until stool and sputum exams are negative for the parasite for 2 weeks.

[c] Safety of praziquantel not established in children less than 4 years old. In endemic areas, risks and benefits of treatment should be considered.

[d] Not available in the United States, not FDA approved.

## Prognosis

Prognosis depends on the extent of the disease. The few deaths described with VT have resulted from myocardial, neurologic, or overwhelming systemic involvement. Neurologic disturbances have been described in severe cases because of invasion of the central nervous system (CNS) by larvae.[35] Seizures, encephalopathy, meningoencephalitis, and transverse myelitis have all been reported. Manifestations of peripheral nervous system involvement include radiculitis and cranial nerve palsy. Renal, pancreatic, and cardiac invasion rarely occur. Cardiac involvement, while rare, can be a potentially life-threatening complication of the disease.[36] *T. canis* also may produce the Pulmonary Infiltrates and Eosinophilia (PIE) syndrome.[37] Finally, various dermatologic manifestations have been reported with toxocariasis.[38] These include chronic urticaria, eczema, and pruritis.

Measures that decrease the ingestion of contaminated soil reduce the incidence of the disease. Anticipatory guidance should focus on the risks of pica and elimination of the behavior. Regular deworming of puppies and lactating or pregnant female dogs should be performed, and the risks of indiscriminate disposal of dog feces, especially in children's play areas, should be emphasized.

Recently, the CDC announced an initiative to prioritize five neglected parasitic infections in the United States, including toxocariasis.[39] Among the major priorities outlined are efforts to better define risk factors and further research to elucidate the natural history of toxocariasis and its complications. There is also a need to develop improved and easily available diagnostic tests for detecting active infection and studies to optimize current treatment regimens using anthelminthic drugs.[29]

# Echinococcosis (Hydatid Disease)

## Epidemiology

Tapeworms of the genus *Echinococcus* are the causative agents of Echinococcosis, which has been recognized as one of the 17 neglected tropical diseases by the World Health Organization (WHO).[40] The disease has a worldwide distribution. It is endemic in most parts of the world where sheep rearing is common including South America, the Mediterranean region, Central Asia, Western China, and East Africa.

There are three major forms of echinococcosis that affect humans: cystic echinococcosis, alveolar echinococcosis, and polycystic echinococcosis. Of these, cystic echinococcosis predominantly affects the lungs, whereas the latter two affect the liver and will not be discussed in detail. Polycystic echinococcosis is the least common form seen and is restricted to South and Central America.[41,42]

Echinococcosis is known to affect all age groups and any body cavity, organ, or site, although it most frequently affects the liver and the lungs, with the lung more commonly affected in children.[41–47] Infection occurs mostly during childhood, although years may elapse before manifestations are seen. While overall there is no gender preference, more cases are reported in males, and this slight difference in gender incidence is probably related to activity or occupation.

## Etiology

Currently, nine species of *Echinococcus* have been identified with the two major species of medical importance being *E. granulosus sensu lato* (formerly recognized as a single species *E. granulosus*) and *E. multilocularis.*[48] Phylogenetic sequencing now shows that there are several different genotypes of *E granulosus sensu lato,* some of which are considered different species.[49] Of these *E. granulosus sensu stricto, E. equinus, E. ortleppi* and *E. Canadensis* all cause cystic echinococcosis. *Enterococcus multilocularis* is the causative agent of alveolar echinococcosis, while *E. vogeli* and *E. oligarthrus* cause polycystic echinococcosis.[48] In addition, another species *E. shiquicus* has been recently described in the Qinghai-Tibet highlands, and while no human disease has been described thus far, further studies are needed.[50] *Echinococcus granulosus sensu stricto* is responsible for the majority (up to 88%) of human cases globally.[48,49]

The parasites are maintained in nature by canines (primarily dogs, coyotes, dingoes, and wolves), which act as the definitive host. Herbivores (sheep, goats, or other livestock) are the intermediate hosts and harbor the larval stage. The life cycles of *E. granulosus, E. multilocularis,* and *E. vogeli* are similar, with the major difference being that the fox is the major definitive host for *E. multilocularis* and rodents are the intermediate hosts for both *E. locularis* and *E. vogeli.* For this review, we will be focusing primarily on *E. granulosus (sensu lato).*

## Pathology/Pathogenesis

The first developmental stage is the tapeworm, which reaches sexual maturity only in the intestinal tract of its definitive mammalian host: dogs or other canines. Adult *Echinococcus* worms typically produce thousands of eggs each day that are extremely resistant to climatic conditions and survive for at least 2 years in northern regions. Infectious ova are released during defecation, contaminating fields, irrigated lands, and wells. Once the eggs are swallowed by humans, the outer shell is digested and the embryos penetrate the intestine and are hematogenously disseminated to various parts of the body, mostly to the liver and lung. In the lung, the embryos form fluid-filled cysts (hydatid cysts) (Fig. 33.1).

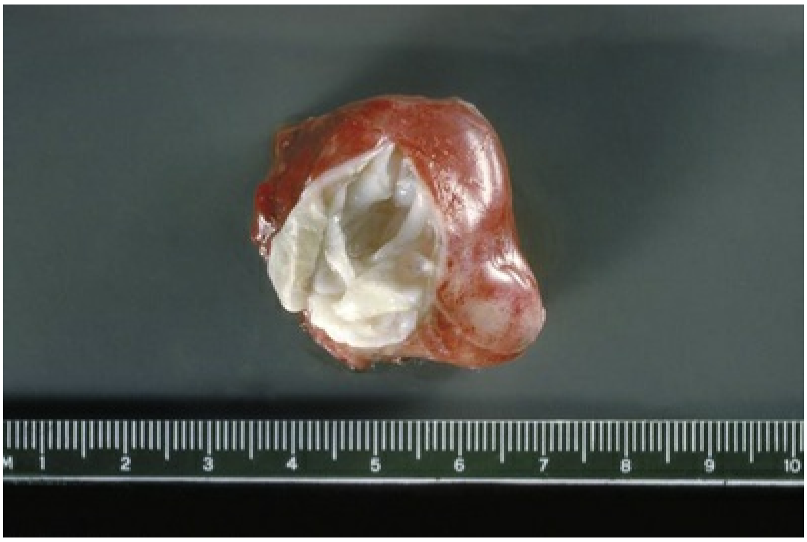

**FIG. 33.1** Gross pathology of membrane and hydatid daughter cysts from human lung.

Under ideal conditions, tapeworm heads, or protoscoleces, develop within the cysts. The minimum time for protoscoleces to develop has been estimated to be 10 months or longer after infection. Humans are accidental hosts and are highly unlikely to be involved in disease transmission. They can become infected from contaminated water and food or through close contact with infected dogs, sheep, or other livestock. Human-to-human transmission does not occur.

Lung cysts develop when embryos pass through the liver, through lymphatic ducts bypassing the liver, by contiguous extension from the liver, or through the bronchi. The cyst slowly enlarges, and its rate of growth is dependent on the distensibility of the tissue and the age of the host. It has also been suggested that different biological attributes such as the rate of attaining fertility as well as the size of a hydatid cyst can be related to the genotype.[40] Pulmonary cysts grow faster in children. At a size of 1 cm, three layers can be identified within the cyst: (1) an inner layer of germinal epithelium or endocyst that is responsible for formation of daughter cysts by endogenous vesiculation; (2) a middle noncellular, laminated layer or ectocyst; and (3) an adventitia or pericyst, an outer capsule of fibrous tissue, vasculature, giant cells, and eosinophils resulting from a weak host reaction. With time, blood capsules and daughter cysts may develop and disintegrate, liberating free floating hooklets or “hydatid sand.”[40]

Involvement of the diaphragm and transdiaphragmatic extension into the lung has been described in patients with primary hydatid cysts of the liver. Virtually any organ including the brain, eye, heart, mediastinum, blood vessels, pleura, diaphragm, pancreas, spleen, endocrine glands, bone, and genitourinary tract may be affected.[47] The CNS is affected more often in children than in adults.

# Clinical Features

## Symptoms

Cyst size, location, and the potential for impairment of vital structures determine the clinical manifestations.[51] The more common symptoms of pulmonary cysts are cough, chest pain, hemoptysis, fever, and malaise. Other manifestations include sputum production, chest discomfort, loss of appetite, dyspnea, vomiting of cyst elements, dysphagia, and hepatic pain.[52–54] Bronchospasm has been reported with relief of "bronchial asthma" after removal of the cyst.[55] Growth retardation patterns have been observed in many children.

A large proportion of pulmonary cases may be discovered incidentally on a routine chest radiograph. The intact cyst is most commonly asymptomatic and may account for a third of all cases. This is usually seen in children where the cyst may be an incidental finding. Most individuals harboring small lung cysts often remain asymptomatic 5–20 years after infection until the cyst enlarges sufficiently to cause symptoms.[56] Awareness of symptoms is due to pressure from the enlarging cyst, secondary infection, and cyst rupture. Up to 30% of lung cysts may be complicated by rupture into the pleural space or bronchus, precipitated by coughing, sneezing, trauma, or increased abdominal pressure. Chills, fever, increased cough, mild hemoptysis, and change in appearance on radiographs suggest rupture.

## Physical Findings

Physical examination is rarely definitive. Occasionally, a hydatid thrill (fluid wave) can be felt while percussing a large cyst. Demonstration of scoleces and hooklets of the parasite in vomitus, stool, urine, or sputum is pathognomonic but is rarely observed and may be seen only during surgery.

Children with echinococcosis may present to the emergency room because of complications of the disease. These complications may be mechanical, with hydatid growth affecting the bronchial tree or pleura; they also may result from hematogenous spread, infection, or allergic reaction. Cyst rupture, pneumothorax, atelectasis, bronchopleural fistula, empyema, saprophytic mycosis have been reported.[55,57,58] A rare complication is rupture into the cardiovascular system with dissemination or sudden death.

Secondary hydatidosis in the pleura, acute asphyxia by bronchial obstruction, and allergic reactions, including anaphylaxis, may follow cyst rupture and leakage.[57] Bronchobiliary fistula occurs in 2% of cases and is commonly, but not always, preceded by suppuration. The right side and posterior basal segment of the lung are most frequently affected. Pyrexia and weight loss may mimic malignancy, but bile expectoration is pathognomonic.

## Imaging, PFT, Laboratory Findings

Lung cysts are readily detected on plain radiographical films, and the possibility of a hydatid cyst should always be considered in an endemic area.[59] An intact cyst is seen as a round or oval homogeneous lesion with a sharply defined smooth border surrounded by normal lung or a zone of atelectasis. It may be located in the periphery, center, or hilum; be single or multiple; and unilateral or bilateral (Fig. 33.2). The final form depends on the location and neighboring structures. With an increase in size, bronchial displacement occurs without obstruction, as has been demonstrated by CT or bronchography. On fluoroscopy, good elasticity of the cyst wall is demonstrable, and there is no interference with movement of the diaphragm.

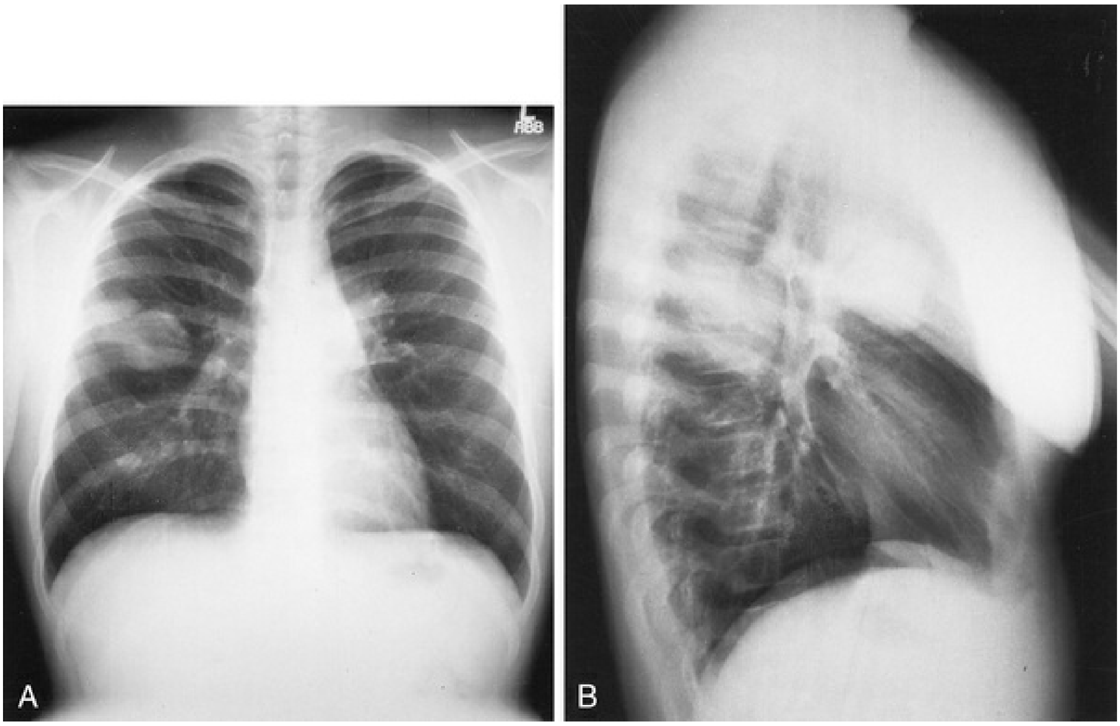

**FIG. 33.2** The posteroanterior (A) and lateral (B) chest radiographs from a 15-year-old boy with cough of several months' duration show bilateral circumscribed densities in the anterolateral right upper lobe and the superior left lower lobe. Histopathology after excision confirmed the diagnosis of hydatid cysts.

As the cyst grows, air passages and surrounding vessels are eroded, producing bronchial air leaks into the cyst adventitia. The bronchial connection is actually nonpatent before rupture because of pressure of the endocyst against bronchial passages, and it may be recognized only during surgery. With varying stages of air dissection into the cyst, different classical radiologic signs may be seen.[59,60] Pericystic emphysema is seen before rupture. A "meniscus sign" or "crescent sign" is a crescentic radiolucency above the homogeneous cyst shadow on deep inspiration that is seen when air penetrates between the adventitia and ectocyst. As air dissection continues, the parasite's membrane is torn, and some hydatid fluid flows out. An air-fluid level is seen within the cyst lumen as well as an air cup between ectocyst and adventitia, known as "double air-layer appearance" or the Cumbo sign. This is also referred to as the onion peel or double arch sign and is pathognomonic for a ruptured pulmonary hydatid cyst.[61] With free connection to a bronchus, the cyst wall is detached from the adventitia, crumbles, collapses, and floats on remaining cyst fluid. This result is seen on the radiograph as air between the collapsed floating cyst wall and the adventitia, known as the "water lily sign" or Camellote sign.[62] The adventitial wall does not collapse at once, so the obliteration of the cyst cavity is not an immediate outcome.

Ultrasonography helps distinguish cystic lesions from solid tumors and has become the diagnostic study of choice for cystic and alveolar echinococcosis due to its low cost and high specificity and sensitivity.[63–66] Pathognomonic signs on ultrasonography are multiple daughter cysts within a cyst, separation of the laminated membrane from the wall of the cyst, and collapsed cysts (Fig. 33.3). A simple cyst with a thick wall in patients from an endemic area is suggestive. Abdominal ultrasonography is also recommended for liver cyst detection. Specific features identified on sonogram are similar to those seen on plain radiographs and include the double-walled cyst, water lily sign, honeycomb appearance, ball of wool sign, and cyst wall calcification with pseudosolid content.[67] The honeycomb sign is caused by multivesiculated cysts in which the walls of adjacent cysts give the impression of "septa." The ball of wool sign is caused by multiple degenerating hypoechoic cyst membranes folded inside the pseudosolid cyst content.

**FIG. 33.3** WHO Informal Working Group on Echinococcosis (IWGE) classification of echinococcal cysts on ultrasound.

Cystic hydatidosis of the lung occurs most often as a single unilocular cyst. Only about 7%–38% occur as multiple unilocular cysts. The inferior lobes are most commonly affected. In children, the ratio of intact to ruptured cysts is 3 : 1, which is the inverse of that in adults. Unlike spleen and liver hydatid cysts, calcification of lung cysts is rare. A high right hemidiaphragm and right basal bronchiectasis suggest bronchobiliary fistula. A tract on sinogram or bronchogram is diagnostic. CT and magnetic resonance imaging (MRI) can also be used and may help with better documentation and definition of the vascular and biliary anatomy in complicated cases (Fig. 33.4).[68,69]

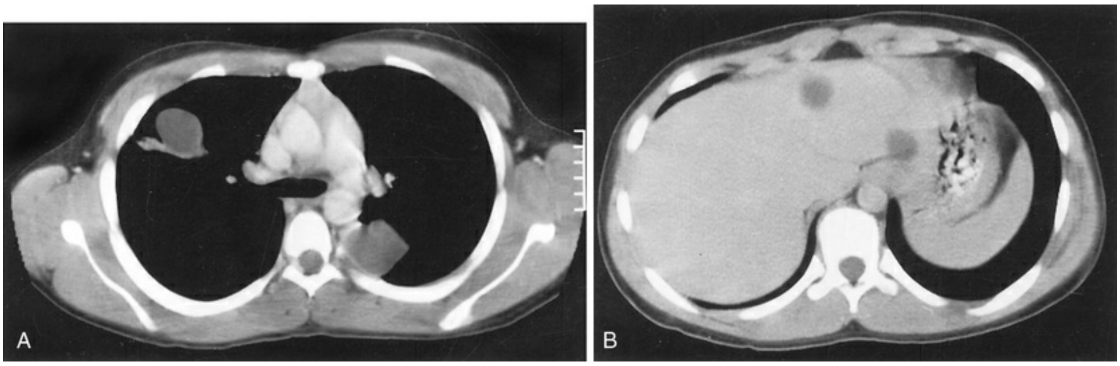

**FIG. 33.4** Computed tomography (CT) of the chest (A) confirms the location of fluid-filled cysts in the anterior right upper lobe and the superior left lower lobe (same patient as in Fig. 33.1), and liver involvement is seen on abdominal CT (B).

Hepatic function may be abnormal in one-half of patients with liver cysts. An increased specific serum IgE may be observed, but eosinophilia is more often absent than present and is completely unreliable in areas endemic for other parasites.

## Diagnosis and Differential Diagnosis

The coughing up of hydatid cyst elements, described as "coughing up grape skins," is diagnostic (see Fig. 33.1). Awareness of the disease is most important. Lung involvement is very likely if a cyst is present elsewhere in the body. Cystic hydatid disease is suspected based on a history of current or previous residence in an endemic area, clinical observations, and radiographic evidence. In 10% of cases, a diagnosis is suspected on routine radiographic study alone.[54] A history of contact with possibly infected dogs may be obtained in only half the cases.

The Casoni skin test involves injection of hydatid fluid in the dermis, which produces an erythematous papule in 50%–80% of patients in less than 60 minutes (Fig. 33.5).[70] False-negative results, sometimes due to infected cysts, and false-positive results occur in 30% of those tested. With the development of improved serologic tests, the Casoni skin test is less commonly used.

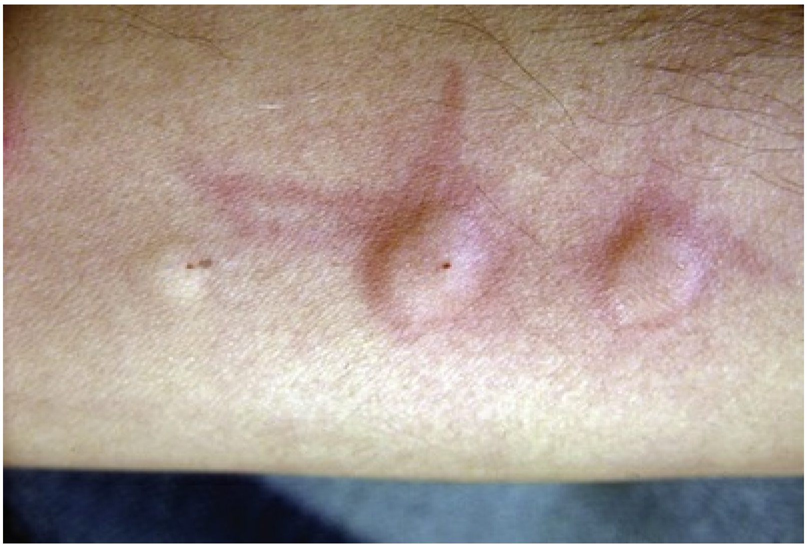

**FIG. 33.5** Casoni reaction.

Serologic tests include latex agglutination, indirect hemagglutination, complement fixation, agar gel diffusion, enzyme immunoassay, and immunoblot.[71,72] Cross-reactivity between echinococcosis and cysticercosis (*Taenia solium* infection) is a problem with any test that employs whole-cyst antigens. Serum antibody testing by indirect hemagglutination is 91% sensitive and 83% specific at a titer greater than or equal to 1 : 128. Immunoblot is 86% sensitive and 99% specific. It has been suggested that the Casoni test and indirect haemagglutination tests be used together in the diagnosis of hydatid disease to establish the diagnosis particularly in endemic areas where this remains a problem.[73] Most recently, rapid diagnostic tests have been developed that may be useful and may complement ultrasound findings in uncertain cases.[74]

After surgical removal of the cyst, there is generally a rapid decline in antibodies within 3 months although they may persist for years. Failure to observe the decline suggests incomplete cyst removal. Serum antibody tests can be referred to the CDC. False-negative results are more common in children and with pulmonary cysts. Up to 50% of patients with hydatid cysts in the lung or calcified cysts are seronegative. Laboratory tests may be more sensitive in complicated cysts, but at present, no single test is infallible, and there is still no serologic test that can effectively rule out the disease. Thus, disease awareness is most important.

Differential diagnosis of hydatid disease includes abscess, hamartoma, pulmonary arteriovenous fistula, benign granuloma, malignant tumor, metastases, and cysts of different origin. When present, the Cumbo sign is pathognomonic.

## Management and Treatment

The treatment options for cystic echinococcosis include surgery, ultrasound-guided aspiration, and chemotherapy. Each method has limitations depending on the specific case. Spontaneous cure is possible after coughing out the cyst and its contents, but more commonly, infection and toxemia follow from the residual cyst. Up to two-thirds of symptomatic patients may die without intervention. Surgery used to be the treatment of choice along with antihelminthic treatment prior to the introduction of ultrasound guided percutaneous drainage, which is now used widely.[75] Endoscopic retrograde cholangiopancreatography should be performed prior to the procedure to ensure that no connections exist with the biliary tree. The acronym PAIR has been used to describe the process that is puncture, aspiration, injection, and then reaspiration.[76] This process has shown a percent reduction in cyst size of 73%–99%.

Once the diagnosis has been confirmed by serology, followed by imaging, the patient should be pretreated with albendazole for a few days prior to percutaneous removal of the cyst.[60] Preoperative treatment has been reported to reduce intracystic pressure and simplify removal. However, it has also been reported that use of albendazole prior to surgery may itself contribute to rupture of the cyst.[77] This is much more likely to occur with large cysts (>6 cm in diameter) due to degenerative changes that occur in the cyst wall. Presurgical use of albendazole or mebendazole can reduce the recurrence of cystic echinococcosis.

Use of albendazole following removal is also controversial.[78] One group suggested treatment should continue for up to 1 month and less if the cyst is smaller (i.e., <6 cm in diameter). In another study, the authors reported that they only used albendazole if there was cyst spillage after surgery, partial cyst removal, or biliary rupture.[79] Most would agree, however, that there is a risk of recurrence if not treated with albendazole as high as 11% in one older report.[80]

Percutaneous removal of hydatid cysts has been reported, but has its limitations and generally cannot be used in the case of multiple cysts or cysts that appear solid, although successful percutaneous drainage of multiple cysts has been reported.

More recently, minimally invasive surgical techniques such as video assisted thoracoscopic surgery (VATS) as well as laparoscopic removal of cysts has also shown to be successful for uncomplicated cysts.[81,82] In addition, techniques such as staged thoracotomy and pneumonostomy have been used for the treatment of multiple lung cysts as well as residual cavities in large complicated cysts.[83,84]

When percutaneous drainage is not possible, surgery is recommended, although conservative management with benzimidazoles may be equally effective in asymptomatic patients.[85] The success of surgery is dependent on the size and location of the cyst and on the skill of the surgeon. If surgery is indicated, it is important to perform surgery immediately after diagnosis, because a weak adventitial reaction and bronchial communications may lead to rupture with intrapulmonary dissemination. Only in the benign Alaskan-Canadian variant is conservative treatment recommended.

The aims of surgery are total eradication of the parasite with evacuation of the cyst and removal of the endocyst, prevention of cyst rupture and consequent dissemination during the operation, along with extirpation of the residual cavity. The lung parenchyma should be preserved and resection should be avoided in children if possible, because the damaged lung parenchyma has great capacity for recovery. Lung resection may be done in cases with bronchiectasis, severe inflammation, and large or multiple cysts that have destroyed lung parenchyma. The posterolateral approach is favored.[60] Surgical techniques to eradicate the parasite may include puncture and aspiration of cysts *in situ*, excision of the entire cyst by enucleation, wedge resection, segmentectomy, lobectomy, or pneumonectomy. Surgical procedures such as enucleation with or without obliteration of the residual cavity by sutures (capitonnage) and cystectomy are mainly used for uncomplicated cysts.[60] Lobectomy or segmental resection is reserved for lungs destroyed by large cysts or bronchobiliary and biliary-pleural fistulas.

The following YouTube video links show removal of hydatid lung cysts both using VATS and open surgical procedures:

https://www.youtube.com/watch?v=1a5DCaSgsuQ
https://www.youtube.com/watch?v=CT-cf-BNazc
https://www.youtube.com/watch?v=SP6qgL8dMZE

Rupture and spillage may occur during surgery and lead to dissemination and anaphylaxis, which can be fatal. This complication, although uncommon even with spillage during surgery, is greatly feared. Anaphylaxis remains a concern, although an extensive literature search showed that lethal anaphylaxis has been a relatively rare event.[86] The differences in surgical techniques therefore reflect the desire to prevent spillage of viable cyst contents. Commonly, the operative field is protected with saline-moistened gauzes, and the cysts are gently manipulated.

After extirpation of the parasite, bronchial fistulas are closed. To prevent recurrence, the residual cavity is injected with scolicidal agents, such as formalin, hypertonic saline, povidone-iodine, or absolute alcohol and albendazole.[87] Because of extremely grave complications with the use of formalin and hypertonic solutions, some have used hydrogen peroxide with good results. The residual cavity is then either obliterated by sutures or left open to communicate with the pleural space. Alternatively, the pericystic membrane is resected with repair of bronchial leakage. Bronchobiliary fistulas may rarely occur following liver hydatid cyst disease. While the management was traditionally thought to be surgical, conservative management has been used with success in less severe cases.[88]

Medical treatment alone has limited success, although results may vary according to the individual case. Between 30% and 50% of cases show some improvement after medical treatment based on imaging findings. Chemotherapy alone is indicated when percutaneous drainage and/or surgery is impractical or impossible, when patients have multiple cysts in two or more organs, when peritoneal cysts are present, and for recurrent disease.[89]

According to the WHO guidelines, benzimidazoles (e.g., mebendazole or albendazole) are the chemotherapeutic agents of choice.[66] Albendazole is the preferred treatment option in the United States, since mebendazole is no longer available in the United States. Albendazole differs from mebendazole in two respects: it is absorbed at a higher rate and it undergoes almost total first-pass metabolism to its effective protoscolicide metabolite, albendazole sulfoxide.[85] Its plasma concentration in hydatid-infested patients is about 10–40 times higher than that achieved with mebendazole. Cyst fluid concentrations also are higher than those achieved with mebendazole. Further enhancement of drug concentration in target tissues may be possible with the concurrent use of cimetidine or administration with a fat-rich meal. Albendazole is usually well tolerated. Liver function may be abnormal in 10%–20% of patients during treatment, but side effects are rarely severe. Use of albendazole has been shown to be a safe and effective alternative to surgery for treating uncomplicated liver cystic *Echinococcosis* and requires a shorter hospital stay. Albendazole should not be used during the first trimester of pregnancy because it has teratogenic effects in animals, although these have not been observed in humans.

Mebendazole interferes with uptake of glucose by cestodes and disrupts their microtubule system, but it is poorly absorbed and produces low blood concentrations.[85] Absorption is enhanced with meals. Repeated courses may be necessary. Cure of hydatid disease has been achieved in 35%–75% of patients, and recurrence rates have been low. Adverse reactions to mebendazole may occur within the first month and include fever and allergic reactions, alopecia, glomerulonephritis, and reversible leukopenia. With hepatobiliary disease, high blood levels and toxicity have been observed. Monitoring of clinical status, liver function, renal function, and complete blood count should be done weekly for the first month and biweekly thereafter.

Patients with chronic liver disease or bone marrow suppression should not undergo benzimidazole treatment. Another benzimidazole compound oxfendazole is available for use in veterinary practice only.

In addition to benzimidazoles, praziquantel may be added especially after surgery, when the risk of spillage is high.[90] Praziquantel when given alone is not effective, but it does act synergistically with albendazole. Although limited data are available, the dose recommended is 40 mg/kg per week.

## Prognosis

The more common surgical complications in children include atelectasis, hydropneumothorax, wound infection, pleural reaction, and hemothorax. Other reported complications from surgery are chest infection, abscess, empyema, septic shock, bronchial rupture, pneumothorax, bronchobiliary and/or biliary-pleural fistula, hemorrhage, massive aspiration, prolonged drainage, bronchiectasis, and allergic reactions, including anaphylactic shock and death with rupture.

The cysts' unusual location is the cause of the following reported rarer complications: arterial emboli, portal hypertension, systemic venous obstruction, paraplegia, pleural effusion, phrenic nerve paralysis, transitory paralysis of cervical sympathetic chain, lower extremity thrombophlebitis, and stress ulcer.[91–93]

Hydatid lung disease is preventable. The use of veterinary taeniacides for dogs; proper disposal of carcasses and entrails of animals to prevent dogs from gaining access; and the proper practice of hand, food, and drink hygiene to prevent contamination from dog excrement are appropriate preventive measures. Follow-up abdominal ultrasonography should be done annually for 5 years or more after successful treatment of hydatid disease. A cyst cavity may remain, and serologic findings may be positive for several years.

## Sylvatic Alaskan-Canadian Variant

The Alaskan-Canadian *Echinococcal* species is clinically and morphologically distinct and has been named *E. granulosus* var. *Canadensis.*[94] It is seen in the tundra and northern coniferous forests of North America, south to the Great Lakes, mainly among the native population, including the Eskimo, Aleut, and Native American Indians, 75% of whom live in areas where *E. granulosus* occurs. The wolf is the definitive host, and sometimes the dog, which ingests the tapeworm by eating the viscera of infected deer. Elk, reindeer, moose, and caribou also are intermediate hosts. Pig, sheep, and cattle resist the infection. In contrast, humans are not very suitable hosts.

The Alaskan-Canadian sylvatic infection is more benign; the cysts are smaller and more delicate, do not grow as rapidly, and produce fewer symptoms than the classic or pastoral *E. granulosus.* The risk of anaphylaxis with rupture is less, and the prospect for spontaneous cure without significant complications is excellent.

Most commonly affected organs are the liver and the lung, with lung involvement in 61% of the cases. Most cysts are simple, intact, and uninfected. For pulmonary cysts, the mean age is 22 years (5–77 years), and for liver cysts, it is 65.3 years (24–96 years). In patients with lung cysts, 71% are younger than 20 years. Only 6%–8% of cases are symptomatic, mostly because of cyst rupture, which occurs in some 26% of patients. Cough, purulent expectoration, and hemoptysis are usual complaints. Serious complications are rare, and no cases of anaphylaxis or seeding have been seen in the Alaskan or Canadian experience.

Diagnosis is based on a history of residence in an endemic area, exposure to dogs, and characteristic findings on routine radiographic study. Typically, a round or oval homogeneous waterlike density with clear-cut borders and no surrounding reaction is seen. Classic signs such as the water lily and crescent sign are rare. Laboratory tests are of little value. Eosinophilia is positive in only 29% of cases, hemagglutination in 10%, and the Casoni test in 56% of cases. With cyst leak or rupture, test results are usually but not always positive.

The surgical risk is minimal. Extrusion of the intact vesicle is not appropriate, and an open wedge resection of adventitia with intact cyst is favored. Gentleness is very important. The bronchial stump should be closed, and the defect in the lung obliterated. Alternatively, cystectomy may be performed.

Quite commonly, the cyst evacuates into the bronchi, and the symptoms disappear. Thus, surgery is not recommended for asymptomatic patients who are managed by observation. No serious morbidity and mortality have been reported with this approach.

# Strongyloidiasis

## Epidemiology

Strongyloidiasis is caused by the nematode *Strongyloides stercoralis.* It is considered one of the most neglected among the neglected tropical diseases.[95] Information on the prevalence of the infection is lacking from many countries; however, it is considered endemic in the tropical and subtropical as well as temperate regions of the world including countries where hygiene and sanitation are lacking; this includes parts of the southeastern United States.[96] Humans are the primary hosts, but primates, cats, and dogs also are frequently infested. Prevalence in the United States has been shown to be 0%–6.1% in selected populations. The numbers among immigrant populations as would be expected are higher, ranging from 0% to 46.1%.[97,98] Infections have also been reported among solid organ transplant recipients.[99,100] A strong association exists between *Strongyloidosis* and immunosuppression such as that seen in patients with malignancies and those on high-dose corticosteroid therapy.[101,102] While once believed to be an acquired immunodeficiency syndrome (AIDS) defining illness in individuals with human immunodeficiency virus (HIV) infection, it is now known that these individuals are not at particular risk for *Strongyloides* infection unless they are immunocompromised due to other concomitant conditions as opposed to HIV infection alone.[103]

## Etiology

The etiologic agent is *Strongyloides stercoralis.* Other species that are known to cause disease in humans include *S. fuelleborni,* while *S. myopotami* and *S. procyonis* are reported to infect animal hosts.[104]

## Pathology/Pathogenesis

The life cycle of *S. stercoralis* is more complex than other nematodes because of its alteration between free-living and parasitic cycles and its potential for autoinfection and multiplication within the human host. The female worm is infectious and lays its embryonated eggs in the intestine; the rhabditiform larvae hatch in the mucosa and then bore through the epithelium and migrate into the intestinal lumen and are excreted in stool. The rhabditiform larvae in the soil, under suitable warm and moist conditions, develop into filariform larvae (direct developmental cycle). However, the rhabditiform larvae can also develop into free-living (nonparasitic) adult male and female helminthes who can mate and lay eggs in the soil (indirect developmental cycle). These eggs then hatch into rhabditiform larvae that can develop into infectious filariform larvae. Similar to the hookworm, these infectious larvae can penetrate human skin, enter the bloodstream, and reach the heart and lungs. In the lung, they molt, climb up the bronchi and trachea, and are swallowed. Once in the intestinal mucosa and crypts, they complete their life cycle. Internal autoinfection can occur, when rhabditiform larvae in the lower bowel develop directly into filariform larvae that in turn penetrate the intestinal mucosa and gain access into lymphatic and hematogenous systems and reach the lung and bowel to complete their life cycle. Massive autoinfection can induce hyperinfection syndrome (HS).[105] Another phenomenon referred to as external autoinfection occurs when the filariform larvae penetrate the perianal skin. The larvae are sensitive to dryness and extreme temperatures.

## Clinical Features

### Symptoms

*Strongyloides stercoralis* infection encompasses five clinical syndromes: (1) acute infection with Loeffler syndrome, (2) chronic intestinal infection, (3) asymptomatic autoinfection, (4) symptomatic autoinfection, and (5) HS with dissemination.[106] The latter is of particular concern in immunocompromised and transplant patients. The pathogenesis of HS may involve disruption in Th 2 cell-mediated, humoral, or mucosal immunity, which triggers conversion of the rhabditiform larvae into filariform larvae, which then migrate from the small intestines to other organs. The mortality of HS is 15% increasing to 87% when there is dissemination.[105,107] Because of the autoinfection phenomenon, patients may have symptoms for years.

Symptoms fall into three broad categories: cutaneous, intestinal, and pulmonary and can occur during acute or chronic disease and during HS. The acute disease is often recognized by its cutaneous manifestations followed by pulmonary and intestinal symptomatology.[108–112] The hallmark of cutaneous symptoms is pruritus at the site of larval entry, usually at the foot or ankle but sometimes also the perianal area. The site of entry has erythema and edema with a petechial or urticarial localized skin rash. Within a week or so, the migration of larvae into the trachea-bronchopulmonary tree causes itching of the throat, dry cough, and Lofflerlike pneumonia with eosinophilia. This is followed by intestinal manifestations that include colicky abdominal pain (often epigastric), diarrhea, flatulence, and malaise.

Symptoms may be recurrent or continuous as the patient enters the chronic stage of the disease. This stage, if not treated, can last decades. With chronic infection, the cutaneous features include stationary urticaria and larva currens (similar to larva migrans).[108] Gastrointestinal symptoms are similar to those in the acute disease and can range from mild to severe. Burning or colicky abdominal pain can accompany diarrhea that can contain blood and mucus and alternate with constipation. In addition, patients may complain of anorexia, nausea, vomiting, flatulence, and perianal pruritus. There also may be epigastric tenderness.

Chronic pulmonary manifestations include dry cough and wheezing. Patients may present with asthma.[113,114] It has been suggested that patients with asthmalike symptoms from endemic areas should be screened for *Strongyloides* infection.[113] With worsening infection, patients may complain of fever, malaise, dyspnea, weakness, and weight loss. One-half of affected patients with chronic strongyloidiasis may be asymptomatic.

HS occurs because of disseminated strongyloidiasis from massive autoinfection, resulting in an overwhelming larval burden and increased dissemination of the larvae to the lungs and other organ systems. This results in severe pulmonary and extrapulmonary systemic symptoms. Although this syndrome can occur without a predisposing cause, it is usually associated with depressed cellular immunity caused by malnutrition, hematologic malignancies, or immunosuppressive therapy (e.g., steroids or anti-tumor necrosis factor [TNF]-$\alpha$).[101,102]

Pulmonary manifestations in patients with HS include increasing cough and dyspnea along with mucopurulent or blood-tinged sputum. Severe hypoxemia may also occur. Occasionally, hemoptysis or pulmonary hemorrhage may be seen.[110] Pneumonia, bronchitis, and pleural effusion have all been associated with *Strongyloides* infection. Rarely, miliary abscesses may form.[115,116]

### Physical Findings

These depend mainly on the extent of the disease. Wheezing, rhonchi, and crackles on lung exam may all be noted. Tenderness on abdominal examination and skin rashes may be present.

### Imaging, PFT, Laboratory Findings

The chest radiograph is normal in most infected patients.[108] During pulmonary larval migration, there may be irregular and transient patches of pneumonitis or fine nodularity.[117] Hyperinfection is accompanied by chest radiographic changes that range from focal to diffuse pulmonary infiltrates, to cavitation and abscess formation.

As with many parasitic infections, peripheral blood eosinophilia is seen, although this is usually absent in HS, since use of corticosteroids reduces the levels of circulating eosinophils by inhibiting their proliferation and increasing apoptosis.[118]

## Diagnosis and Differential Diagnosis

Similar to the other helminthic infections, the diagnosis of strongyloidiasis is best made by visual identification. For *S. stercoralis,* identifying the characteristic rhabditiform larvae in stool, sputum, or duodenal fluid is diagnostic. However, a single stool specimen has a sensitivity of only 15%–30%.[108,117] Stool concentration techniques may be required. Sensitivity increases to nearly 100% if seven consecutive daily stool specimens are examined in an expert laboratory, although this may not always be very practical. Serologic tests (gel diffusion and ELISA) are sensitive but often cross-react with other filarial parasites, thus limiting their usefulness, particularly in endemic settings. PCR of stool has been developed but may not be widely available, particularly in resource-poor countries.[118–121] CDC can provide confirmation of serologic tests that are equivocal or difficult to interpret.[122]

The combination of cutaneous, intestinal, and pulmonary symptoms, with eosinophilia on peripheral smear, and potential exposure in an endemic area provide essential clues for making the diagnosis. Pulmonary symptoms should be differentiated from pneumonitis caused by TB, mycoses, paragonimiasis, ascariasis, tropical pulmonary eosinophilia, and Löffler syndrome due to other causes.

The treatment is medical, and the goal is elimination of all the worms; therefore, repeated treatment is sometimes needed. Ivermectin is the drug of first choice followed by albendazole (see Table 33.1).[123,124] Thiabendazole in a dose of 25 mg/kg twice daily for 2–3 days (or 2–3 weeks for HS) has also been used and appears to have equal efficacy to Ivermectin with fewer side effects. Thiabendazole is only available for veterinary use in the United States; however, it is still used in other countries.[124] A recent report described the use of the veterinary preparation of Ivermectin in two patients with severe HS with successful outcomes.[125] After completion of initial treatment, patients must be followed for years to ensure complete eradication of all worms.

Screening strategies should be considered in patients who may be particularly vulnerable to *Strongyloides* infections.[126–128] These include patients who are on or about to start corticosteroid or other immunosuppressant therapy, those known to have human T-lymphotropic virus (HTLV)-1 infection, individuals with hematologic malignances, those about to undergo organ transplantation, those with persistent and unexplained eosinophilia, and individuals with recent or remote travel histories to endemic areas. As with any of the other parasitic infections, the best method of prevention includes proper disposal and treatment of sewage material.

# Pulmonary Paragonimiasis (Lung Fluke Disease)

## Epidemiology

Paragonimiasis, also known as lung fluke disease, Japanese lung fluke, oriental lung fluke, and pulmonary distomiasis, is caused by the genus *Paragonimus* and causes a zoonotic infection of carnivorous animals, including those in the canine and feline families (which also serve as reservoir hosts). Most human disease is caused by *Paragonimus westermani* and occurs following consumption of raw, undercooked, or alcohol pickled crustaceans (namely shellfish). Occasionally ingestion of raw meat from a mammalian host may also cause the disease.[129] The disease is endemic in parts of Southeast (SE) Asia (including China, Philippines, Thailand, Vietnam, and Japan) but is also seen in North America and Africa. More than 30 species have been reported worldwide with at least 10 that can infect humans. Paragonimiasis is rare in children, because they are less likely to indulge in consumption of exotic food and because this helminth is not transmitted by fecal-oral transmission, by person-to-person contact, or from consumption of infested water.

## Etiology

Apart from *P. westermani,* other species that can cause human disease include *P. heterotremus, P. skrjabini,* and *P. miyazakii,* which are all found predominantly in Southeast Asia; *P. africanus* and *P. uterobilateralis* in Africa; and *P. caliensis* and *P. mexicanis* in South and Central America. *P. kellicotti* is the only species that is endemic in North America.[130–132]

## Pathology/Pathogenesis

*P. westermani* adult lung cysts have two adult flukes in them that lay eggs that reach the bronchi of the mammalian host either by penetrating the intact cyst wall or through rupture of the cyst wall. From the bronchi, the eggs reach the mouth and are either spit out or swallowed and then excreted in stool. In the water, these eggs embryonate and hatch in approximately 3 weeks. The hatched miracidium invades the first intermediate host (one of several families of snails), and after a protracted asexual cycle, they form sporocytes that turn into cercariae. These then enter the second intermediate host (crustaceans); here they encyst and form the infectious metacercariae that reach the definitive mammalian host. Once eaten by the definitive host, the metacercariae encyst in the duodenum, penetrate the intestinal wall to reach the liver, and change into flukes. These flukes migrate through the diaphragm into the lung. In the lung, over a period of 5–6 weeks, they mature into adult flukes and are encysted as a result of host immune response. Adult flukes begin to lay eggs 8–10 weeks after the infection. Human infection occurs by eating crustaceans that contain the parasite metacercariae.

As the life cycle of the fluke suggests, it can cause both pulmonary and extrapulmonary disease involving the brain, liver, skin and rarely eyes as well as other parts of the body.[129,133–136] The lesions are a result of direct mechanical damage by the flukes or their eggs or by the toxins released by the flukes. The host response also adds to the damage in the lungs when the host immune response takes the form of eosinophilic infiltration and the subsequent development of a cyst of host granulation tissue around the flukes. Besides the adult flukes, the cyst also contains eggs and Charcot-Leyden crystals.[137] The cysts are in the parenchyma of the lungs close to the bronchioles. The release of cyst contents can cause bronchopneumonia, and the cyst wall may fibrose and become calcified. In extrapulmonary infections, the flukes may form cysts, abscesses, or granulomata.

# Clinical Features

## Symptoms

The symptoms depend on the site infected and the infectious burden. Some individuals may remain asymptomatic because of low inoculum burden. Pulmonary paragonimiasis has acute and chronic stages with different clinical manifestations. The main clinical manifestations of paragonimiasis are respiratory symptoms and eosinophilia. Once the flukes reach the lungs, the patient can have cough, dyspnea, and chest tightness or even pain; systemic symptoms of fever, malaise, and night sweats may also be present. The patient may recall being sick days or weeks before their current illness with fever, diarrhea, and abdominal pain. Chills and urticarial rash may occur, leading to the diagnosis of a viral syndrome. A peripheral smear at this time shows eosinophilia. The diagnosis of paragonimiasis is frequently not made in the acute stage of the disease. The chronic stage usually follows 2–4 months later. Most patients look well, and the disease may resemble chronic bronchitis or bronchiectasis with a worsening cough that starts out dry and becomes productive and profuse. The sputum is gelatinous and blood streaked or rusty brown in color. Hemoptysis can be frequent and life threatening.[138] Low-grade fever along with vague pleuritic chest pain may be present. Patients also may have weight loss and complain of muscular weakness. Given the similarity of the clinical complaints, patients are frequently misdiagnosed and treated for pulmonary TB.[139–142]

## Physical Findings

In uncomplicated pulmonary paragonimiasis, the chest examination may be remarkably normal. Children rarely have digital clubbing. Other physical findings would depend on disease manifestations. Pulmonary paragonimiasis can be complicated by lung abscess, pneumothorax, pleural adhesions, empyema, and interstitial pneumonia. As noted previously, pulmonary disease may be associated with abdominal (hepatic or peritoneal) and cerebral disease.

## Imaging, PFT, Laboratory Findings

Chest radiography may be normal in acute pulmonary paragonimiasis, or it may show peribronchitis and hilar lymphadenopathy. However, in chronic paragonimiasis, chest radiography may show various abnormalities, including patchy nodular or linear infiltration, well-defined homogeneous densities, pleural thickening, effusion, and calcification.[143,144] The pathognomonic radiographic picture shows a ring shadow with a crescent-shaped opacity along one side of the border.[145] CT scan may define the cavities much better.[146] In addition, the detection of a migration track may also help narrow the differential and point to the diagnosis.[147] Similar findings may be seen on MRI.[148] On routine laboratory investigation, eosinophilia may be seen although leukocytosis is not common. Pleural fluid findings may include eosinophilia and increased lactic dehydrogenase levels, as well as low glucose[139]

## Diagnosis and Differential Diagnosis

History is important in the diagnosis. In the United States, the most likely patient is a refugee, a recent immigrant, or someone with a recent history of travel. Similar to other protozoal infections, the definitive diagnosis can be made by identifying the characteristic golden brown, ellipsoidal operculated protozoal eggs. The characteristic operculated eggs can be identified in sputum or stool specimens, although the sensitivity of the tests is low. Repeat examination may increase the sensitivity of these tests. Bronchoalveolar lavage also has been successful in identifying the eggs and making the diagnosis. In complicated pulmonary paragonimiasis, the eggs can be identified in pleural fluid or lung abscess material. Rarely, adult flukes can be identified in the sputum. Serologic tests using various techniques (immunoblot, counterimmunoelectrophoresis, complement fixation, and ELISA) are sensitive (96%) and specific (99%).[149] They are more useful in diagnosing extrapulmonary paragonimiasis. Skin testing cannot be used to make a diagnosis.

Pulmonary TB is the major differential diagnosis because the same endemic areas also have a high prevalence of TB. Other conditions to consider include bronchial asthma, chronic bronchitis, pulmonary neoplasm, and other parasitic infections endemic for the region.

## Management and Treatment

Treatment is with praziquantel 25 mg/kg 3 times daily after meals for 2 days (see Table 33.1). Cure rates greater than 95% have been reported.[150] Another drug used more recently with promising results is triclabendazole.[150]

## Prognosis

Prevention efforts should be aimed at educating the public against the use of untreated fresh water for drinking or cooking and avoiding improperly prepared or raw crustaceans.

# Principles of Mechanical Ventilation

*Bhushan Katira MB, BS, DNB, Takeshi Yoshida MD, PhD, Brian P. Kavanagh MB, FRCPC*

## History

Historical descriptions of artificial respiration include 18th-century devices for intubation, bag and mask ventilation, and application of negative extrathoracic pressure.[1] The widespread use of mechanical ventilation (MV) did not occur until the polio outbreaks of the 1950s when iron lungs (negative pressure chambers) were deployed. Bjorg Ibsen, a Danish anesthesiologist, was the first to deploy positive pressure ventilation for the care of these patients as the iron lung did not prevent aspiration and was inefficient in the presence of significant atelectasis.[2] Approximately 200 medical students manually ventilated patients via tracheostomies, and the overall mortality was 25%, compared with an anticipated rate of 90%. This laid the foundation for modern critical care medicine. Since then, devices for MV have become more sophisticated facilitating synchrony between the patient and the ventilator, the use of graphics, added measurements, and user friendliness.

# Indications for Mechanical Ventilation

In most situations, the indications for MV are evident. The principal indications for MV in the critically ill are inadequate respiratory effort, or to recruit lung units and improve oxygenation. Causes of inadequate respiratory effort include a sustained increase in respiratory and metabolic demand (e.g., pneumonia, asthma, lung injury, sepsis, or metabolic acidosis), or underlying neuromuscular failure, such as acute or chronic paresis or fatigue.

MV is used during general anesthesia if respiration is inhibited or blocked by deep sedation, opioids, or neuromuscular blockade. Indications for intubation also include "protection" of the airway, when the patency of the airway is diminished from proximal airway obstruction due to edema or tumor, or is at risk from the aspiration of gastric contents or hemorrhage; in such situations, MV is usually added.

In addition to providing a "pumping" action that facilitates tidal gas exchange, MV is also used to provide elevated airway pressure, which recruits collapsed lung units (or maintains local recruitment), thereby improving oxygenation.

Finally, ventilation may be used in an emergency to provide hyperventilation when hypocapnia is temporarily sought in the management of acute intracranial hypertension.

# Composition of a Mechanical Ventilator

The ventilator consists of a gas delivery system, in addition to several subsystems (Fig. 34.1). The delivery system in turn consists of a breath controller, a mode controller, and a demand sensor. The breath controller generates the flow (i.e., the tidal volume [$V_T$]), which may be entirely derived from the ventilator, or in part, from the patient's effort.

**FIG. 34.1** Basic ventilator design principle. The schematic illustrates the essential components of a mechanical ventilator: gas delivery system, gas blender, and patient circuit.

There are three elements at play in the delivery of a $V_T$. First, the breath is triggered (by ventilator timing, or is initiated by the detection of patient inspiratory effort). Second, the flow of gas is controlled either by attaining a certain pressure, or volume, during inspiration. If "pressure" is targeted, then the inspiratory gas flow will vary depending on the difference between the pressure in the airway at the trachea (measured) and that in the alveoli (not measured), and will decrease as the inspiration progresses. If the "volume" is targeted, then the volume is delivered equally during each fraction of the inspiratory time (i.e., at a constant flow rate). Third, the ventilator "cycles off," to end inspiration and permit (passive) exhalation; as with initiating inspiration, cycling off can be initiated by ventilator timing or by detecting the patient's expiratory effort.[3]

Where initiation or termination of inspiration is governed by the patient, effort sensors are key. These detect changes in pressure (or flow), and the sensitivity (how sensitive is the ventilator to change in airway pressure or flow) and responsiveness (speed of response by the ventilator to such a change) of "effort sensors" are major determinants of satisfactory patient-ventilator interaction.[4]

Important additional components include gas blenders that mix air (21% $O_2$) and oxygen (100% $O_2$) to achieve the required $F_IO_2$. An "expiratory pressure generator" is required to maintain a certain pressure in the airway during expiration (termed: positive end-expiratory pressure, PEEP), to recruit atelectatic lung units, or to prevent their collapse.

Effective humidification and temperature control of the inspired gas is achieved by the use of special humidifiers, and the gas delivery circuit connects the ventilator to the interface (usually an endotracheal tube [ET], noninvasive ventilation mask, or ventilation hood).

## Modes of Ventilation

Modes of MV can be described in terms of the type of "control" (pressure vs. volume) and the initiation of the breath (Fig. 34.2).[5]

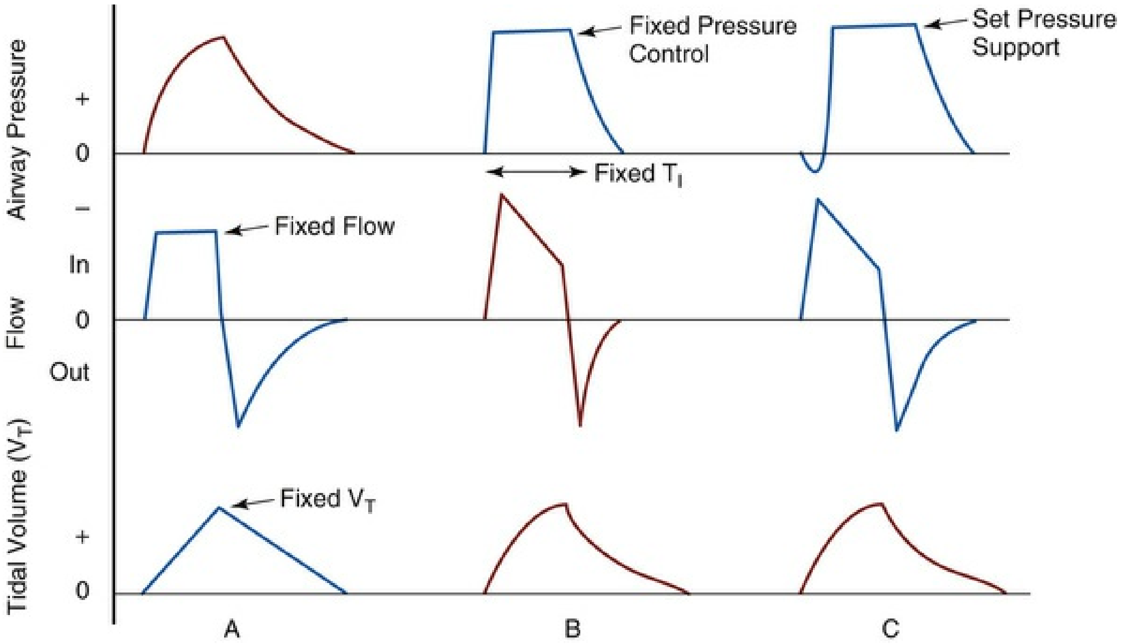

**FIG. 34.2** Basic ventilation modes. The graph depicts changes in pressure, flow, and volume during a respiratory cycle for three commonly used modes: volume control (A), pressure control (B), and pressure support (C) ventilation. In volume control ventilation (A), tidal volume *($V_T$)* is determined by the clinician, and so the inspiratory flow (volume per minute) is therefore also fixed. The pressure required to achieve the tidal volume depends on the lung compliance and

resistance (which may change from breath to breath). During pressure control ventilation (B), the pressure, as well as the start time, duration, and finishing time of the inspiration are decided by the clinician. The resulting $V_T$ depends on the lung compliance and resistance. Pressure support ventilation (C) is a spontaneous mode during which the breath is triggered by the patient (negative airway pressure deflection). The level of support (i.e., inspiratory airway pressure; pressure support) is chosen by the clinician. Inspiration ends and expiration begins when the inspiratory flow rate decreases to a predetermined level (usually 20%–30% of peak inspiratory flow). In contrast to pressure control ventilation, where inspiration is started and stopped by the ventilator timing, inspiration in pressure support ventilation is controlled by the patient. $V_T$, Tidal volume; $T_I$, inspiratory time.

The control reflects either volume or pressure. Volume control ventilation indicates that the $V_T$ is predetermined. Because the inspiratory time is fixed, the volume is delivered through inspiration at a constant flow ("square wave" pattern); thus, inspiratory pressure reflects any changes in lung mechanics. The $V_T$ is controlled at the set value by the ventilator, and is delivered independent of the chosen level of PEEP.

In pressure control ventilation the inspiratory pressure is constant; therefore, the pressure-time waveform is a "square wave" pattern. The flow (therefore the volume) of gas, which depends on the pressure difference between the ventilator (gas source) and the alveoli (gas destination), diminishes over time (as the lungs fill). In addition, any changes in compliance, resistance or patient effort will alter the flow (but not the pressure). The initiation and termination of a pressure control breath depend on timing, that is the rate (breaths per minute), and the duration of inspiration ($T_I$), which are set on the ventilator.

In pressure support ventilation, the profile of pressure and principles of flow are the same as in pressure control. However, the initiation of a breath needs to be triggered by an inspiratory effort by the patient; in contrast, termination of inspiration occurs when the inspiratory flow rate falls to 20%–30% (chosen by the clinician) of the peak (initial) inspiratory flow rate, which occurs when a patient attempts to exhale.

The “type” of breath is the second main factor, and this describes the interaction between the patient and the ventilator. Continuous mandatory ventilation (CMV) indicates that the ventilator provides all the work of breathing (WOB); indeed, there is no ability for the patient to breath as the ventilation is set by the clinician and cannot be altered by the patient.

Assist control (AC) indicates that the patient can initiate (trigger) the breath, but as soon as the inspiration has been initiated, the ventilator completes the breath. The clinician sets the “minimum” (or back-up) number of breaths per minute, which is the number of breaths that will occur if the patient makes no effort. However, each breath initiated by the patient will be completed by the ventilator (regardless of the rate). Weaning is difficult with this mode, because every breath results in a full $V_T$—even if the AC rate is set to a low value—and this readily leads to hyperventilation.

With intermittent mandatory ventilation (IMV), the ventilator provides intermittent mandatory breaths based on the set minute ventilation; however, between these breaths, patients can make their own breaths that are not altered (assisted, completed, or inhibited) by the ventilator. In contrast to AC, patient breaths are not assisted by the ventilator; therefore, weaning the IMV rate means that the patient can make intermittent breaths of variable size without resultant hyperventilation.

Modern IMV is “synchronized” so that the ventilator sets windows of time each minute during which if a sufficient $V_T$ is not completed by the patient it will be completed by the ventilator; synchronization means that these windows are reset every time an adequate $V_T$ has occurred. This helps achieve better patient–ventilator synchrony.[6]

Continuous spontaneous ventilation refers to a simple mode wherein most of the WOB is done by the patient; the ventilator provides constant pressurization of the circuit (continuous positive airway pressure, CPAP), on which pressure support (see above) can be superimposed.

Although important for understanding the classification of ventilators, pure forms of CMV or IMV are almost never used in contemporary practice.

## Noninvasive Ventilation

Noninvasive ventilation (NIV) describes the delivery of mechanical support through an interface (e.g., nasal prongs or mask, face mask, or helmet) and without the need for an ET. NIV offers the ability to reduce patient WOB and improve respiratory gas exchange while avoiding the risks and complications related to the placement of an ET, including sedation and neuromuscular blockade. In addition, it can easily be initiated during transport or in settings where intubation in not commonly performed.[7]

Conventional NIV is delivered using nasal cannula, nasal mask, full face mask, and helmet. A full-face mask or helmet more reliably provides positive airway pressure, but it may cause agitation, especially in infants and younger children, and has a greater dead-space (requiring high flows to clear the $CO_2$). A nasal cannula or mask is often better tolerated but a pressure leak due to a poor interface seal or through the mouth may limit effectiveness.

NIV is designed to either deliver CPAP: Continuous distending pressure for the whole respiratory system) or bilevel positive airway pressure (BiPAP: two levels of positive airway pressure—inspiratory and expiratory). BiPAP is either synchronized (spontaneous) with each patient effort or with a defined back up rate (Timed).

NIV is particularly used in bronchiolitis, asthma, pneumonia, pulmonary edema, cystic fibrosis, acute chest syndrome, laryngotracheomalacia, and acute hypoxemic failure. Contraindications to the use of NIV include cardiopulmonary arrest, the inability to protect upper airway, poor neurological status, shock (requiring escalating vasopressors), upper gastrointestinal bleed, facial injuries, and untreated pneumothorax. The appropriate selection of interface and mode of NIV are key to optimizing support for children. It is clinically titrated to WOB, heart rate, subjective comfort, and oxygenation. Frequently BiPAP is used for ventilation failure; therefore, the effect is measured as efficacy of $CO_2$ removal.

Air leak syndrome, aspiration, and hemodynamic instability from cardiac preload reduction are serious but rare complications, whereas gastric distension and facial skin breakdown are more common. The inability to humidify the gas may lead to nasal/oral mucosal damage. Eye irritation, trauma, and inflammation can also result from improper mask fit and continuous exposure to high gas flow.

Heated high flow $O_2$ is a newer delivery system used to deliver gas flow rates of up to 8 L/min in an infant (or about 60 L/min in large child). It allows delivery of flow rates higher than the patient's peak inspiratory flow with fixed $FiO_2$. It generates PEEP of 2–5 cm $H_2O$, reduces WOB, improves tolerance of the oxygen delivery system, and reduces the need for intubation. It is particularly helpful in children with bronchiolitis and airspace disease without ventilation failure.[8] Importantly, it does not guarantee a fixed airway pressure, and thus may generate lower transpulmonary pressure than NIV, when a patient adds a significant inspiratory effort to the external ventilator support.

## High-Frequency Ventilation

High-frequency ventilation (HFV) applies continuous distending pressure to maintain lung expansion, and superimposes small $V_T$s at a rapid rate; the main type of HFV used is high-frequency oscillatory ventilation (HFOV). The small $V_T$s result from oscillating air movements produced by the ventilator diaphragm or piston at frequencies of 600–900 breaths per minute (10–15 Hz), which result in both positive (inspiratory) and negative (expiratory) pressure fluctuations.

Two major concepts differentiate HFOV and so-called conventional ventilation (although HFOV has been in use for over 40 years). First, $CO_2$ is cleared despite using a $V_T$ that is less than physiological dead-space, a phenomenon that is not possible using standard “bulk flow” kinetics. However, with HFOV, multiple mechanisms contribute to $CO_2$ removal. Second, $CO_2$ removal (which is increased by greater $V_T$, but not in a linear relationship), is increased by decreasing the frequency; this counterintuitive finding is because with a lower rate, the time to develop a $V_T$ is increased, and this increases $CO_2$ clearance.

In most circumstances, the major use for HFOV is lung recruitment, and this is primarily a function of the mean airway pressure employed, and is assessed in terms of oxygenation response. The other key adjustments are the amplitude and frequency of the pressure wave, to achieve $CO_2$ clearance, as well as the inspired $O_2$ concentration ($FiO_2$).

HFOV has a long history in pediatric critical care. One subset of potential priority is ventilated children with neonatal pulmonary hypertension (e.g., congenital diaphragmatic hernia), where the major rationale is enhanced $CO_2$ clearance (below).

## Neurally Adjusted Ventilator Assistance

Conventional MV tracks changes in airway pressure (and flow), and the assumption is that these parameters account for changes in the patient's respiratory "need" (i.e., respiratory drive). However, increased respiratory drive may not translate into increased diaphragmatic contraction, perhaps due to partial paralysis or muscle weakness. Further, increased diaphragm contractility may not translate into an adequately negative deflection of the pressure–time curve during expiration, due to lung injury and poor pressure transmission from the pleural space to the airway. Because the conventional ventilator only senses changes in airway pressure (or flow), there may be a significant discrepancy between the patient "need" (i.e., phrenic nerve output to the diaphragm) and the level of support supplied by the ventilator.[9]

Neurally adjusted ventilator assistance (NAVA) senses the electric activity of the diaphragm ($EA_{di}$), which is independent of ventilator, circuit, and respiratory mechanics, using a catheter embedded in a gastric tube. When electrical activity is greater than a set threshold (0.5 μV) a mechanical breath is delivered; the size of the breath (of level of pressure) is based on the amplitude of $EA_{di}$ and the level of assistance determined by the clinician. This results in breath-to-breath variation of $V_T$, and adjustment is made to the assist level such that a satisfactory $V_T$ is delivered and a diminished $EA_{di}$ signal is detected that reflects lessened patient demand. This approach should improve patient comfort and prevent over or under ventilation, relative to neutrally determined need.

## Hemodynamic Effects of Mechanical Ventilation

The most important hemodynamic effects of MV are the impact on ventricular preload and afterload (Fig. 34.3). Positive ventilator pressure increases alveolar pressure and lung volume, and compressed the heart and the great veins in the thorax. Therefore, the compressed veins and right atrium can accommodate lower blood volume (than with spontaneous ventilation, i.e., “negative pressure”), and thus the venous return and preload (i.e., end-diastolic volume) are decreased. The lower preload results in a lower stroke volume, and therefore a lower cardiac output, which if severe, will result in hypotension. Patients particularly susceptible to the impact on preload are those with hypovolemia, tamponade, air trapping (e.g., status asthmaticus), or those in incipient shock from any cause. The optimization of intravascular volume may mitigate this problem.

Spontaneous Breathing
Positive Pressure Breathing

**FIG. 34.3** Effect of positive pressure on hemodynamics. The schematic illustrates key effects of mechanical ventilation on preload (A) and afterload (B). During spontaneous breathing, the intrathoracic pressure is negative and the RA pressure is low; this draws blood into the thorax. During positive pressure, the intrathoracic pressure is positive and the major veins, RA and RV are compressed. This reduces venous return and, hence, the preload to the right (and

left) heart. During spontaneous ventilation, due to negative intrathoracic pressure, the transmural LV pressure (i.e., pressure inside—pressure outside) is higher, whereas during positive pressure ventilation the transmural LV pressure is lower, but the inside pressure remains unchanged. Thus, positive pressure ventilation reduces LV wall stress and increases cardiac output. *AO*, Aorta; *LVSP*, left ventricular systolic pressure; *PA*, pulmonary artery; *RA*, right atrium; *RV*, right ventricle; *SV*, systemic veins.

The effects of positive pressure ventilation on "compressing" the heart may be beneficial if the ventricle is less sensitive to reduced preload, but more sensitive to increased afterload. The afterload against which the ventricle contracts is the ventricular wall stress (i.e., the "transmural" pressure divided by the wall thickness):

$$\begin{aligned}&\text{Ventricular afterload}\\&\quad=[\text{pressure inside}-\text{pressure outside}]/(\text{wall thickness})\end{aligned}$$

Thus, positive pressure, by increasing the "outside" (i.e., pericardial = pleural, pressure) decreases wall stress, and this effect is proportionally greater if the ventricular performance is impaired (i.e., generates lower values of intraventricular pressure). In this situation, positive airway pressure assists the ventricle to eject, and provided the preload is adequate, this increases the cardiac output. In situations where the afterload is limiting the ventricular output (e.g., impaired contractility, mitral valve regurgitation), positive pressure ventilation increases cardiac output.

Finally, the effects of MV are especially useful in cardiogenic pulmonary edema where the rate of formation of edema is slowed, due to lower venous return to the thorax; and, the cardiac output is increased, which augments forward flow of blood out of the lungs.

## Mechanical Ventilation in Specific Conditions

### Normal Lungs

General anesthesia is certainly the commonest indication for MV and most of these children have normal lungs. Here, evolving clinical evidence (from adult studies) raises the possibility that high $V_T$ should be avoided in patients with normal lungs during general anesthesia. Children are commonly intubated (and ventilated) in the setting of encephalopathy, brain injury, or neuromuscular weakness (e.g., Guillain-Barré syndrome, myopathy, etc.), because of either impaired airway protection (e.g., inadequate airway reflexes or cough strength) or hypoventilation.

The main complications include atelectasis of dependent lung, or rarely, ventilator-associated pneumonia. The use of PEEP, endotracheal toilet, and the prevention of airway contamination offset most of these issues. Depending on the primary illness, recovery of strength and level of consciousness may be delayed, and tracheostomy may be indicated to maximize comfort, and to facilitate nursing care as well as weaning from MV.

## Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is an acute pathological condition characterized by inflamed, atelectatic lungs, resulting from an underlying condition (most commonly sepsis). While pathologically it is represented by characteristic histology termed "diffuse alveolar damage," it is suspected clinically in the setting of an acute respiratory deterioration accompanied by pulmonary infiltrates and impaired oxygenation. MV in these patients serves to reduce the WOB, and provide increased airway pressure to recruit atelectatic lung.

Perhaps the most important issue, having secured adequate oxygenation, is to minimize ventilator-associated lung injury (VALI). The mainstay of this approach is avoidance of high $V_T$ although the optimum $V_T$[10] for children with ARDS, or for any child in particular, is not known.

A key principle in ventilator management is to keep the lung "open," and this likely represents sound practice in cases where it is possible. The use of recruitment maneuvers, and the maintenance of the recruited lung (if recruitable) with elevated PEEP, is a standard approach. Where higher levels of PEEP are being contemplated (especially where the chest wall is noncompliant, e.g., obesity), an esophageal manometer might be used to determine the (real) transpulmonary distending pressure and thereby permit use of higher levels of PEEP. Alternative approaches to recruitment include prone positioning or the use of HFOV.

## Status Asthmaticus

In status asthmaticus, ventilation failure due to exhaustion from prolonged or profound airway obstruction, is the major indication for assisted ventilation. Such failure is usually manifest as the inability to speak more than one or two words, or as a diminished level of consciousness.

In many cases, noninvasive ventilation with CPAP (or bi-level ventilation, BiPAP) can be effective via a facemask, while aggressive bronchodilator therapy and steroids are administered. The impact of positive airway pressure may be two-fold. First, there may be a simple reduction in the WOB due to the ventilator assistance with inspiration. Second, in rare cases, the positive airway pressure may maintain patency of the distal airways that are closed because of raised pleural pressure from intense expiratory effort; in this situation, the positive pressure “stents” open the airways and facilitate exhalation. Endotracheal intubation is reserved for cases in which NIV is ineffective; this is fraught because laryngeal and tracheal stimulation can worsen bronchospasm, and should involve expert airway management whenever possible.

## Bronchiolitis

Bronchiolitis due to childhood respiratory viruses is often complicated by airway inflammation, obstruction, mucus plugging, and atelectasis. This culminates in increased work of breathing (WOB) and impaired gas exchange. NIV or High Flow $O_2$ can reduce WOB by distending the airway and preventing its collapse, but progressive increases in WOB or worsening hypoxemia may be indications for invasive ventilation. Dynamic hyperinflation also can be a problem due to widespread bronchial inflammation, although mucus plugging is more common. Thus, balancing PEEP to reduce hyperinflation, and opening areas of atelectasis, is important. In this situation, $V_T$ is targeted to 6–8 mL/kg, and the respiratory rate is titrated to allow better expiration.

## The Neonate

Premature newborns may need respiratory support at birth for resuscitation, respiratory distress syndrome (RDS), persistent pulmonary hypertension (PPHN), sepsis, or simply to facilitate growth and development.[11]

During neonatal resuscitation, intubation is often elective and the duration of MV variable; however, in neonatal RDS, MV is specifically used to reduce WOB. In addition, MV facilitates the delivery of surfactant, and the prevention of elevated pressure after surfactant delivery is key to avoiding the pulmonary air leak syndrome.

PPHN is an entity unique to neonates, where oxygenation failure occurs in the absence of acute lung disease or congenital heart disease; here, there is a prepost ductal oxygenation gradient reflecting profound pulmonary hypertension (which can be identified and quantified using an echocardiogram). The goal of MV in this disease is to provide $O_2$, recruit lung (if recruitable), and to assist in clearing $CO_2$ to minimized respiratory acidosis and to alleviate pulmonary hypertension. The use of HFOV in this setting (as in congenital diaphragmatic hernia) should exploit the technique's unique ability to effectively clear $CO_2$ in neonates, and should not be used to recruit (nonrecruitable) lung; the mechanism of improved oxygenation is usually through the relief of pulmonary hypertension, and thereby reduced right to left shunting. The judicious use of high $FiO_2$ (a pulmonary vasodilator), longer $T_{Ins}$, lowering $PaCO_2$, and the use of inhaled nitric oxide are important elements in the management of PPHN.

## Congenital Heart Disease

In patients with elevated pulmonary blood flow (e.g., caused by a large left-to-right shunt or single ventricle physiology), the use of lower $FiO_2$, adequate PEEP to maintain functional residual capacity, and hypercapnia to increase pulmonary vascular resistance, may each help limit pulmonary blood flow.

Where the pulmonary blood flow is primarily low (e.g., teratology of Fallot), adjusting the level of PEEP and $V_T$ volume may allow increased lung blood flow. With a Glenn circulation, (bidirectional cavo-pulmonary shunt), the presence of hypercapnia increases cerebral blood flow, and thereby increases pulmonary perfusion. In addition, early extubation (and resumption of spontaneous ventilation) may be beneficial in right heart failure, and the Glenn and Fontan circulation. In contrast, for left heart failure or mitral regurgitation, positive pressure ventilation augments cardiac output.

# Management During Mechanical Ventilation

## Monitoring

Monitoring assists in the ongoing management of all patients. The key monitoring of the ventilated child is for comfortable ventilation, including oxygenation and WOB. Deterioration in WOB mandates immediate attention to consider the status of the underlying condition and the possible development of a complication, such as a poor mask fit, obstructed or dislodged ET, or ventilator equipment failure. In the sedated and paralyzed patient pulse oximetry, end-tidal carbon dioxide and blood gas analysis are especially important. Chest roentgenography may help to determine the ET position, the evidence of air leak, and the development of new infiltrates, in addition to monitoring the baseline condition for which MV was instituted.

## Comfort

The presence of an ET, as well as pain from operative incisions or following trauma, coupled with anxiety associated with being in the intensive care unit, warrant judicious use of sedation and analgesia. This will assist in optimizing patient-ventilator synchrony.

## Suctioning

Normal airway ciliary action, and coughing, moves respiratory secretions towards the mouth but the presence of the ET tube impedes this process, and an impaired cough, due to sedation (and perhaps paralysis), compounds the problem. Secretion volume and tenacity are increased with pulmonary infection or inflammation, and thus secretion clearance is a problem. Therefore, the presence of pneumonia, ARDS, bronchiolitis, or especially pulmonary hemorrhage, mandates careful and thorough suction, often with irrigation, to prevent airway occlusion from inspissated secretions.

## Synchronization

Patient-ventilator dyssynchrony manifests as respiratory distress while receiving MV, and this is often observed as “fighting” the ventilator. This requires a careful review, first of the patient, to ensure that deterioration in the underlying condition or a treatable complication (e.g., blocked or displaced ET tube, pneumothorax) have not developed. The nature of the dyssynchrony then needs to be carefully examined to determine if the level of support (pressure, $V_T$, respiratory rate, $FiO_2$) is sufficient for the patient's demands, and, thereafter, if the patient is able to trigger the ventilator.[6] In many cases, the first step is to disconnect the ventilator circuit from the ET to facilitate independent assessment of the patient. Discomfort may cause asynchrony (and certainly asynchrony can be uncomfortable); determining the cause, and optimizing sedation and analgesia, is important.

## Gas Humidification

The gas in the ventilator circuit is dry and can cause airway erosion. When ventilating children, humidification of the air-oxygen mixture is achieved by a chamber in the inspiratory limb of the ventilator circuit that contains water at 2–3°C above body temperature. In larger children, passive humidification can be accomplished by inserting a heat-moisture exchanger between the circuit and the ET.

## Fluid Management

Aside from during active resuscitation, fluid restriction is preferred in most mechanically ventilated patients, because the insensible losses due exhaled humidified air are minimal. In addition, positive pressure ventilation can cause fluid retention (reduced renal perfusion, increased secretion of antidiuretic hormone). Obviously, the assessment of ongoing fluid losses will dictate the approach.

## Weaning and Extubation

Weaning is the process of transferring all WOB from the ventilator to the patient. While a major problem in debilitated adults, this appears to be less of an issue in pediatric critical care medicine. The major concerns in preparing for extubation are adequacy of respiratory drive, muscle strength for coughing and ventilation, airway integrity, oxygenation, adequacy of analgesia (in burns or postoperative cases) and fluid status.[6] A brief trial of spontaneous breathing (T-piece, flow inflating bag) will make clear the child's respiratory drive and the neuromuscular status; it is usually not necessary to slowly reduce ventilator settings, and most children who are awake and pain-free can simply be extubated. Finally, planning should always address the likely cause of respiratory failure (should it occur) in a child before extubation, as well as the approach to airway management, if required.

## Neuromuscular Blockade

Neuromuscular blockade is commonly used in ventilated patients. It may be an important component of care in specific settings such as intracranial hypertension, or more recently, in patients with ARDS (likely to minimize the additive lung injury from strong spontaneous effort superimposed on mechanical breaths). A major concern is use of paralysis when a patient is distressed: care must be taken that the airway is secure and that ET malposition is not the cause of agitation. In addition, sedation must be sufficient to prevent awareness during paralysis.

## Complications of Mechanical Ventilation

Positive pressure ventilation can injure lungs directly, and this is called VALI; it primarily results from use of high $V_T$s. This problem likely compounds any underlying lung injury (e.g., from pneumonia), and worsens the outcome. Pressure-induced damage (barotrauma) causes pulmonary air leak syndromes, which can vary from pulmonary interstitial emphysema to pneumothorax or bronchopleural fistula. Excessive recruitment maneuvers, extreme levels of PEEP, or high inspiratory pressure, lead to this kind of injury. Although 6 mL/kg is a widely recommended $V_T$ for adults with ARDS, the optimal $V_T$ in children is unknown.

Ventilator induced diaphragmatic dysfunction is being increasingly recognized and results from disuse (or overuse) of the diaphragm during MV. Steroids and paralysis can aggravate this problem.

Ventilation associated pneumonia (VAP) is defined as onset of new lung infection within 48 hours of intubation and ventilation. It is thought to result from aspiration of oropharyngeal secretions. However, VAP is poorly understood and most centers now look to alternative quality measures to manage the issue.

Subglottic stenosis secondary to intubation occurs in 1%–2% of intubated children in the intensive care unit. The incidence increases with the length of intubation, traumatic intubation, and preexisting airway inflammation. Steroids can reduce airway inflammation and may reduce the chances of subglottic stenosis. A subset of children may eventually need laryngoplasty to treat this condition.

## Conclusion

MV is a life-saving supportive therapy in critically ill children, and is deployed for a variety of indications. Choosing the optimal mode, defining the goals, optimizing mechanics and gas exchange, enhancing patient–ventilator synchrony, and preventing ventilator-associated complications, are important principles of practice. Finally, ongoing monitoring and expert care are the keys to success.

# Childhood Pulmonary Arterial Hypertension

*Usha Krishnan MD, DM, Erika Berman-Rosenzweig MD*

## Introduction

Pulmonary arterial hypertension (PAH) is a serious progressive condition with a poor prognosis if not identified and treated early. Until recently, the diagnosis of idiopathic pulmonary arterial hypertension (IPAH, formerly termed primary pulmonary hypertension [PPH]) was virtually a death sentence, particularly for children, with a median survival of less than 1 year.[1–4] The data in the Primary Pulmonary Hypertension-National Institutes of Health (PPH NIH) Registry illustrated the worse prognosis for children than adults.[1] In this registry, the median survival for all of the 194 patients was 2.8 years, whereas it was only 0.8 years for children. Fortunately, there has been promising progress in the field of PAH over the past several decades, with significant advances in treatment that can improve quality of life, exercise capacity, hemodynamics, and survival.[5–7] Nevertheless, extrapolation from adults to children is not straightforward. This chapter will review childhood PAH, with an emphasis on the latest therapeutic advances.

## Definition and Classification

In children, per the pediatric American Heart Association/American Thoracic Society (AHA/ATS) guidelines, PAH is defined as having a mean pulmonary artery pressure (PAPm) ≥25 mm Hg at rest, beyond 3 months of age at sea level with a normal pulmonary artery wedge pressure (<15 mm Hg), and an elevated pulmonary vascular resistance (PVR > 3 Wood Units × $m^2$). PH is defined as mPAP >25 mm Hg in children >3 months of age at sea level. PAH occurs in the "precapillary" pulmonary vascular bed and therefore excludes causes of pulmonary venous hypertension (e.g., mitral stenosis). Although exercise hemodynamic abnormalities are no longer included in the updated definition of PAH, they may still be an important measure in some children, because children with PAH often have an exaggerated response of the pulmonary vascular bed to exercise.[8,9] The exclusion of exercise-induced PAH was based on the difficulty in reliably obtaining complete exercise hemodynamics and the concern that some subjects could be misdiagnosed as having exercise-induced PAH. Children also have a greater vasoreactive response to hypoventilation than adults. Not uncommonly, children with a history of recurrent exertional or nocturnal syncope have a resting PAPm that markedly increases with exercise and with modest systemic arterial oxygen desaturation during sleep.

## Evolution of the Classification of Pulmonary Hypertension

The first WHO World Symposium in 1973 classified PH into primary and secondary PH. In 1998, at the second World Symposium in Evian, clinical investigators from around the world proposed a new diagnostic classification; this classification categorized pulmonary vascular disease by similar clinical features, histopathology, hemodynamics, and management. PH was classified into five basic groups: PAH (group 1), left heart disease (group 2), lung disease (group 3), chronic thromboembolic PH (CTEPH; group 4), and multifactorial PH (group 5). At the 2003 Venice meeting, the term "PPH" was changed to "IPAH," reflecting the fact that this is a diagnosis of exclusion with exact cause(s) yet unknown.[10–12] Thus, in addition to IPAH (both sporadic and familial), PAH associated with congenital heart disease (CHD); connective tissue disease (CTD); portal hypertension; HIV infection; drugs and toxins (including anorexigens); and persistent pulmonary hypertension of the newborn (PPHN) were classified along with IPAH as group I PAH. In 2008 at Dana Point, the diagnostic classification system was updated further, and the term "familial pulmonary arterial hypertension" (FPAH) was abandoned in favor of heritable PAH (HPAH), defined to include all subjects with FPAH, plus any patients with an identified genetic mutation, regardless of whether there was a family history of PAH. Pulmonary veno-occlusive disease and pulmonary capillary hemangiomatosis, which share many similarities with group I PAH but have subtle variations, was separated out to group I′. Finally, in 2013, at the fifth World Symposium held in Nice, France, although the basic framework was maintained, it was decided in conjunction with the pediatric PH task force to add elements related to pediatric PH and have a comprehensive classification common for all age groups, reflecting the understanding that many children with PH will grow up to become adults with PH (Box 35.1).[11]

## Box 35.1

## Updated Clinical Classification of Pulmonary Hypertension

1. Pulmonary arterial hypertension
    - 1.1 Idiopathic PAH
    - 1.2 Heritable PAH
        - 1.2.1 BMPR2
        - 1.2.2 ALK 1, ENG, **SMAD9, CAV1, KCNK3**
        - 1.2.3 Unknown
    - 1.3 Drug and toxin induced
    - 1.4 Associated with:
        - 1.4.1 Connective tissue disease

- 1.4.2 HIV infection
- 1.4.3 Portal hypertension
- 1.4.4 Congenital heart diseases
- 1.4.5 Schistosomiasis

**1′ Pulmonary veno-occlusive disease and/or Pulmonary capillary hemangiomatosis**
**1″ Persistent Pulmonary Hypertension of the Newborn (PPHN)**

2. Pulmonary hypertension due to left heart disease
    - 2.1 Left ventricular systolic dysfunction
    - 2.2 Left ventricular diastolic dysfunction
    - 2.3 Valvular disease
    - 2.4 **Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies**
3. Pulmonary hypertension due to lung diseases and/or hypoxia
    - 3.1 Chronic obstructive pulmonary disease
    - 3.2 Interstitial lung disease
    - 3.3 Other pulmonary diseases with mixed restrictive and obstructive pattern
    - 3.4 Sleep-disordered breathing
    - 3.5 Alveolar hypoventilation disorders
    - 3.6 Chronic exposure to high altitude
    - 3.7 Developmental lung diseases
4. CTEPH
5. Pulmonary hypertension with unclear multifactorial mechanisms
    - 5.1 Hematologic disorders: **chronic hemolytic anemia,** myeloproliferative disorders, splenectomy
    - 5.2 Systemic disorders: sarcoidosis, pulmonary histiocytosis, lymphangioleiomyomatosis
    - 5.3 Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
    - 5.4 Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure, **segmental PH**

*BMPR,* Bone morphogenic protein receptor type II; *CAV1,* caveolin 1; *CTEPH,* chronic thromboembolic pulmonary hypertension; *ENG,* endoglin; *PAH,* pulmonary arterial hypertension; *PH,* pulmonary hypertension.

Although the classification helps our understanding of the pathophysiology of PAH patients, it also has implications for the natural history. Despite the different physiologic classifications of group 1 PH, the histopathologic changes are virtually identical, so similar treatment strategies have evolved. As insight is advanced into the mechanisms responsible for the development of PAH, the introduction of novel therapeutic modalities will hopefully increase the overall efficacy of therapeutic interventions for PAH. In 2011, the members of the pediatric task force of the pediatric pulmonary vascular research institute (PVRI) proposed a functional classification of PH in children that describes assessment of functional capacity in children of different age groups, as well as a 10-category scheme of further categorizing pulmonary hypertensive vascular disease in children (Boxes 35.2 and 35.3).[13,14] They divided the functional classes to class I, II, IIa, IIb, and IV, and also described them separately for age groups 0–0.5 years, 0.5–1 year, 1–2 years, 2–5 years, and 5–16 years. Of particular importance is the acknowledgement of single ventricle circulation, where pulmonary vascular disease may be present without a mean PAP reaching 25 mm Hg, as these patients may benefit from targeted therapy.[14,15] Thus the definition of PAH may be further expanded in single ventricle circulations to include a transpulmonary gradient of >6 mm and a PVRi >3 WU × $m^2$.[15,16]

## Broad Schema of 10 Basic Categories of Pediatric Pulmonary Hypertensive Vascular Disease

| CATEGORY | DESCRIPTION |
|---|---|
| 1 | Prenatal or developmental pulmonary hypertensive vascular disease |
| 2 | Perinatal pulmonary vascular maladaptation |
| 3 | Pediatric cardiovascular disease |
| 4 | Bronchopulmonary dysplasia |
| 5 | Isolated pediatric pulmonary hypertensive vascular disease (isolated pediatric PAH) |
| 6 | Multifactorial pulmonary hypertensive vascular disease in congenital malformation syndromes |
| 7 | Pediatric lung disease |
| 8 | Pediatric thromboembolic disease |
| 9 | Pediatric hypobaric hypoxic exposure |
| 10 | Pediatric pulmonary vascular disease associated with other system disorders |

*PAH,* Pulmonary arterial hypertension.

**Box 35.3**

## Detailed Classification of Pediatric Pulmonary Hypertensive Vascular Disease

1. Prenatal or developmental pulmonary hypertensive vascular disease
    - 1.1. Associated with maternal or placental abnormalities
        - 1.1.1 Preeclampsia
        - 1.1.2 Chorioamnionitis
        - 1.1.3 Maternal drug ingestion (nonsteroidal antiinflammatory drugs)
    - 1.2. Associated with fetal pulmonary vascular maldevelopment
        - 1.2.1. Associated with fetal pulmonary hypoplasia
            - 1.2.1.a. Idiopathic pulmonary hypoplasia
            - 1.2.1.b. Familial pulmonary hypoplasia

    - 1.2.1.c. Congenital diaphragmatic hernia
    - 1.2.1.d. Hepatopulmonary fusion
    - 1.2.1.e. Scimitar syndrome
    - 1.2.1.f. Associated with fetal pulmonary compression
      - oligohydramnios
      - omphalocele/gast
      - cystic adenomatosis
      - fetal tumors or masses
    - 1.2.1.g. Associated with fetal skeletal malformations
  - 1.2.2. Associated with fetal lung growth arrest/maldevelopment
    - 1.2.2.a. Acinar dysplasia
    - 1.2.2.b. Congenital alveolar dysplasia
    - 1.2.2.c. Alveolar capillary dysplasia with/out misalignment of pulmonary veins
    - 1.2.2.d. Lymphangiectasia
    - 1.2.2.e. Pulmonary artery abnormalities
    - 1.2.2.f. Pulmonary venous abnormalities
- 1.3. Associated with fetal cardiac maldevelopment
  - 1.3.1. Premature closure of foramen ovale or ductus arteriosus
    - 1.3.1.a. Idiopathic
    - 1.3.1.b. Drug induced
  - 1.3.2. Congenital heart defects associated/causing pulmonary vascular disease in the fetus
    - 1.3.2.a. Transposition of the

                great arteries (TGA) with intact ventricular septum
            - 1.3.2.b. Hypoplastic left heart syndrome with intact atrial septum
            - 1.3.2.c. Obstructed total anomalous pulmonary venous connection
            - 1.3.2.d. Common pulmonary vein atresia
- 2. Perinatal pulmonary vascular maladaptation (persistent pulmonary hypertension of the neonate, PPHN)
    - 2.1. Idiopathic PPHN
    - 2.2. PPHN associated with or triggered by
        - 2.2.1. Sepsis
        - 2.2.2. Meconium aspiration
        - 2.2.3. Congenital heart disease
        - 2.2.4. Congenital diaphragmatic hernia
        - 2.2.5. Trisomy[13,18,21]
        - 2.2.6. Drugs and toxins
            - Diazoxide
- 3. Pediatric heart disease
    - 3.1 Systemic to pulmonary shunts
        - 3.1.1. PAH associated with systemic to pulmonary shunt with increased PVRi, no R-L shunt
            - 3.1.1.1. Operable
            - 3.1.1.2. Inoperable
        - 3.1.2 Classical Eisenmenger syndrome
            - 3.1.2.1. Eisenmenger–simple lesion (ASD, VSD, PDA)
            - 3.1.2.2. Eisenmenger–complex lesion (truncus, TGA/VSD, single ventricle)
        - 3.1.3. Small defect with elevated pulmonary arterial pressure/PVRI out of proportion to the size of the defect
            - Coexistent with pulmonary

hypoplasia
Coexistent with inherited or idiopathic pulmonary hypertensive vascular disease

- 3.2. Postoperative pulmonary arterial hypertension following
  - 3.2.1. Closure of shunt with
    - 3.2.1.1 Persistent increase in PVRI>3 WU × m$^2$
    - 3.2.1.2 Recurrent increase in PVRI>3 WU × m$^2$
  - 3.2.2. Arterial or atrial switch operation for TGA with intact ventricular septum
  - 3.2.3. Repair of left heart obstruction
  - 3.2.4. Repair of tetralogy of Fallot
  - 3.2.5. Repair of pulmonary atresia with VSD and MAPCAs
  - 3.2.6. Surgical aortopulmonary shunt
- 3.3. Pulmonary vascular disease following staged palliation for single ventricle physiology
  - 3.3.1. After stage 1 (PA banding, modified Norwood, hybrid procedure, aortopulmonary or ventricular pulmonary shunt, stenting PDA)
  - 3.3.2. After SVC to PA anastomosis (Glenn)
  - 3.3.3. After total cavopulmonary anastomosis (Fontan)
- 3.4. Pediatric pulmonary hypertensive vascular disease associated with congenital abnormalities of the pulmonary arteries/veins
  - 3.4.1. PPHVD associated with congenital abnormalities of the pulmonary arteries
    - 3.4.1.1. Origin of a pulmonary artery from the aorta
    - 3.4.1.2. Unilateral isolation/ductal origin/“absence” of a

      - pulmonary artery
    - 3.4.2. PPHVD associated with congenital abnormalities of the pulmonary veins
      - 3.4.2.1. Scimitar complex
      - 3.4.2.2. Pulmonary vein stenosis
      - 3.4.2.3. Cantú syndrome[157]
  - 3.5. Pulmonary venous hypertension
    - 3.5.1. Pulmonary venous hypertension due to congenital left heart inflow or outflow disease: aortic stenosis, aortic incompetence, mitral stenosis, mitral regurgitation, supramitral ring, pulmonary vein obstruction, cor triatriatum, endocardial fibroelastosis, left ventricular hypoplasia/Shone complex, congenital cardiomyopathy, restrictive atrial septum in hypoplastic left heart syndrome
    - 3.5.2. Pulmonary venous hypertension due to acquired left heart disease
      - Left-sided valvar heart disease (rheumatic/postendocarditis arthritis)
      - Restrictive/dilated/hypertroph cardiomyopathy
      - Constrictive pericardial disease
- 4. Bronchopulmonary dysplasia
  - 4.1 With pulmonary vascular hypoplasia
  - 4.2 With pulmonary vein stenosis
  - 4.3 With left ventricular diastolic dysfunction
  - 4.4 With systemic to pulmonary shunts
  - 4.5. With significant hypercarbia and/or hypoxia
- 5. Isolated pediatric pulmonary hypertensive vascular disease (PPHVD) or isolated pulmonary arterial hypertension (PAH)
  - 5.1. Idiopathic PPHVD/Idiopathic PAH

- 5.2. Inherited PPHVD/PAH
    - 5.2.1. BMPR2
    - 5.2.2. ALK 1, endoglin
    - 5.2.3. Unidentified genetic cause
- 5.3. Drugs and toxins
    - 5.3.1. Definite association: toxic oil
    - 5.3.2. Likely association
        - Amphetamine
    - 5.3.4. Possible association
        - Cocaine
        - Methylphenidate
        - Diazoxide
        - Cyclosporin
        - Phenylpropanolamine
- 5.4. Pulmonary veno-occlusive disease (PVOD) and/or pulmonary capillary hemangiomatosis[156]
    - 5.4.1 Idiopathic PVOD
    - 5.4.2 Inherited PVOD

6. Multifactorial pulmonary hypertensive vascular disease associated with multiple congenital malformations/syndromes
    - 6.1. Syndromes with congenital heart disease
    - 6.2. Syndromes without congenital heart disease
      Both 6.1 and 6.2 may include VACTERL, CHARGE, Poland, Adams-Oliver Syndrome, Scimitar complex, Trisomy, Di George, Noonan, von Recklinghausen disease, Dursun syndrome, Cantú syndrome
7. Pediatric lung disease
    - 7.1. Cystic fibrosis
    - 7.2. Interstitial lung diseases: surfactant protein deficiency, etc.
    - 7.3. Sleep-disordered breathing
    - 7.4. Chest wall and spinal deformities
    - 7.5. Restrictive lung diseases
    - 7.6. Chronic obstructive lung diseases
8. Pediatric thromboembolic disease causing pulmonary hypertensive vascular disease

- 8.1. Chronic thromboemboli from central venous catheters
  - 8.2. Chronic thromboemboli from transvenous pacing wires
  - 8.3. Ventriculoatrial shunt for hydrocephalus
  - 8.4. Sickle cell disease
  - 8.5. Primary endocardial fibroelastosis
  - 8.6. Anticardiolipin/antiphospholipid syndrome
  - 8.7. Methylmalonic acidemia and homocystinuria
  - 8.8. Due to malignancy: osteosarcoma, Wilms tumor
  - 8.9. Post splenectomy
- 9. Hypobaric hypoxic exposure
  - 9.1. High-altitude pulmonary edema (HAPE)
  - 9.2. Infantile subacute mountain sickness
  - 9.3. Monge disease
  - 9.4. Hypobaric hypoxic exposure associated with
    - PPHN
    - Congenital heart disease
    - Isolated PPHVD or PAH
- 10. Pulmonary hypertensive vascular disease associated with other system disorders
  - 10.1. Pediatric portal hypertension
    - 10.1.1. Congenital extrahepatic portocaval/portosystemic shunt (e.g., Abernethy syndrome, left atrial isomerism, trisomy,[21] portal vein atresia or thrombosis)
    - 10.1.2. Liver cirrhosis
  - 10.2. Pediatric hematological disease
    - 10.2.1. Hemolytic anemias: β-thalassemia, sickle cell disease
    - 10.2.2. Post splenectomy
  - 10.3. Pediatric oncologic disease
    - 10.3.1. Pediatric pulmonary arterial hypertension associated with malignancy
    - 10.3.2. Pulmonary veno-occlusive disease after bone marrow transplantation and chemotherapy[156]

- 10.4. Pediatric metabolic/endocrine disease
    - 10.4.1. Gaucher disease
    - 10.4.2. Glycogen storage disease[1,111]
    - 10.4.3. Nonketotic hyperglycinemia
    - 10.4.4. Mitochondrial depletion syndrome
    - 10.4.5. Mucopolysaccharidosis
    - 10.4.6. Hypothyroidism/hyperthyroidism
- 10.5. Pediatric autoimmune or autoinflammatory disease
    - 10.5.1. POEMS
    - 10.5.2. Mixed connective tissue disease
    - 10.5.3. Scleroderma–limited and diffuse disease
    - 10.5.4. Dermatomyositis
    - 10.5.5. Systemic lupus erythematosis (SLE)
    - 10.5.6. Antiphospholipid/anticardiolipin syndrome
    - 10.5.7. Systemic-onset juvenile arthritis
    - 10.5.8 Pulmonary veno-occlusive disease and SLE[156]
- 10.6. Pediatric infectious disease
    - 10.6.1. Schistosomiasis
    - 10.6.2. HIV infection
    - 10.6.3. Pulmonary tuberculosis
- 10.7. Pediatric chronic renal failure
    - 10.7.1 Pulmonary arterial hypertension predialysis and with hemodialysis or peritoneal dialysis
    - 10.7.2 Pulmonary veno-occlusive disease after renal transplantation

Cerro MJ Del, Abman S, Diaz G, et al. A consensus approach to the classification of pediatric pulmonary hypertensive vascular disease: Report from the PVRI Pediatric Taskforce, Panama 2011. *Pulm Circ*. 2011;1(2):286-298.

## Epidemiology and Etiology

Because PAH remains an "orphan" disease with multiple potential etiologies, registries have been developed to better describe the populations with PAH and categorize them into various etiologies and study the disease epidemiology better.[1,18] McLaughlin et al. discussed the importance of the various registries and stressed their role in generating future prospective studies of the clinical course and management of a rare disease like PH.[19,20] The Dutch national pediatric PH registries suggested an annual incidence of 0.7 cases per million for IPAH, and a prevalence of 4.4 per million and 2.2 and 15.6 cases per million children with CHD-PAH.[21,22] Two major registries describing the adult populations are the French registry, which reported a distribution of IPAH 39.2%, FPAH 3.9%, CTD 15.3%, and CHD 11.3%, whereas the Registry to Evaluate Early And Long-term PAH Disease Management (REVEAL) registry revealed slightly different estimates of IPAH 42.7%, FPAH 2.7%, CTD 25%, and CHD 10%.[8,23,24] The pediatric pulmonary hypertension network (PPHNet) is currently establishing a registry of pediatric pulmonary hypertension in the United States and Canada, and results are pending.[25] Studies from national databases in countries with centralized care for PAH, such as France and Britain, have been very helpful in estimating the prevalence of the disease.[26,27] The UK registry reports an incidence and prevalence of 0.48 per million and 2.1 per million children for IPAH, and the French study reported a prevalence of 2.2 cases per million children. CHD-PH is more common in children as compared with adults; however, with increasing survival of CHD patients into adulthood, these statistics are rapidly changing. A report on the treatment and survival of children from the national pediatric PH service in the United Kingdom over a 5-year period from 2001 to 2006 showed that 60/216 patients had IPAH and 156 had associated pulmonary arterial hypertension (APAH).[10,12,18] Of the APAH group, there were 49 patients with Eisenmenger syndrome (ES), 47 repaired CHD, 29 chronic lung disease, 9 CTD, and 8 complex CHD. The mean age in the UK report for IPAH was 7.4 years, and the French registry reported a mean age at inclusion of 8.9 years. The mean age at diagnosis of the 216 pediatric patients recruited from 54 centers in the United States included in the REVEAL registry was 7 years.[8,28]

## Gender

The gender distribution in adults is weighted toward more women with IPAH, whereas in pediatric patients, this distribution has been more variable, depending on the inclusion criteria, with female to male ratio varying from 1.09 : 1 in the French and Swiss registries to 1.7 : 1 reported by the UK group. Other studies have found a more even gender distribution, with the Dutch study reporting 55% of IPAH patients to be female.[22,29] When all etiologies of PAH are included, the female to male ratio gets closer to 1 : 1 because there is no significant gender predominance for CHD with PAH. The REVEAL registry reported a 2 : 1 female to male ratio in children and a 4.1 : 1 in adults with IPAH.[8]

## Genetics of PAH

The first report of familial PPH was published as early as 1954 by Dresdale, and since then it has been increasingly evident that heritable PAH has a very strong association with germline mutations.[30–33] By the1980s it was evident that FPAH had an autosomal dominant mode of inheritance, and by 1997, two independent groups localized the defect to a region on chromosome 2 Q33. Mutations of the transforming growth factor β (TGFβ) family of receptors, particularly bone morphogenetic protein receptor (BMPR2), are found in kindreds with FPAH. More than 300 germline BMPR2 mutations have been identified in FPAH patients, with the mutations being usually similar within families. These mutations are located throughout the gene. BMPR2 mutations are seen in more than 80% of patients with HPAH, while the remaining have mutations in other genes encoding the TGFβ superfamily of receptors. In addition, mutations of ACVRL 1, activin receptor–like kinase 1 (ALK 1) located on chromosome 12, and endoglin (ENG) on chromosome 9 have been described in association with hereditary hemorrhagic telangiectasia (HHT).[34–36] A third locus, the SMAD8 gene identified on chromosome 13, ties in with the role of SMADs in BMP signaling.

The BMPR2 mutations are germ line mutations and are potentially heritable, regardless of whether they appear de novo in an index case or have been inherited. Because of reduced penetrance, only approximately 20% of people with a BMPR2 mutation develop the disease. Females have a greater incidence and prevalence of HPAH, suggesting either that the male fetuses with the disease die in utero or there are hitherto undetected risk factors increasing the predilection for developing the disease in women. The clinical expression of PAH is variable, even within families having the same mutation. Genetic anticipation has been described with HPAH (i.e., affected individuals in successive generations in a family pedigree express the disease earlier with earlier age of death); however, this has been recently been questioned.[37] BMPR2 mutations are seen in 80% of subjects with FPAH and are also seen in approximately 10%–25% of patients with no family history of PAH, suggesting that these represent de novo mutations. Individuals with BMPR2 mutation have more severe disease phenotype associated with earlier disease manifestation, worse hemodynamics, less vasoreactivity, and earlier mortality.[30] This is also seen with the ACVRL 1 mutation.[36] Male carriers of the BMPR2 mutations tend to have a worse prognosis. It has been suggested that genetic testing for BMPR2 mutations be performed in children with PAH and healthy siblings. Because of the large number of potential mutations in the gene, and the fact that mutations within a given pedigree are constant, testing should start with the proband and then the family members of the affected individual.

Whole exome sequencing (WES) techniques have shown a rare mutation in the caveolin 1 (CAV1) gene in members of a family with PAH.[34] More recently, a novel channelopathy has been described in the potassium channel (KCNK3), which may have implications for finding a therapeutic pathway.[38]

# Neonatal Pulmonary Hypertension

## Persistent Pulmonary Hypertension of the Newborn

PPHN is a unique form of PAH, which usually resolves completely with appropriate intervention. PPHN is a syndrome characterized by increased PVR, right to left shunting (at the atrial and/or ductal level), and severe hypoxemia.[39] It is frequently associated with pulmonary parenchymal abnormalities (e.g., meconium aspiration, pneumonia, or sepsis) or may occur when there is pulmonary hypoplasia, maladaptation of the pulmonary vascular bed postnatally as a result of perinatal stress, or maladaptation of the pulmonary vascular bed in utero from unknown causes. In some instances, there is no evidence of pulmonary parenchymal disease and the cause of PAH is unknown. Although some children die during the neonatal period despite maximal cardiopulmonary therapeutic interventions, PPHN is almost always transient, with infants recovering completely without requiring long-term medical therapy. In contrast to these infants, patients with IPAH, as well as PAH related to the other conditions discussed previously, appear to require treatment indefinitely. It is possible that in some neonates the PVR does not fall normally after birth and goes unrecognized during the neonatal period; the patient is then diagnosed with PAH at a later date as the pulmonary vascular disease progresses. Pathologic studies examining the elastic pattern of the main pulmonary artery suggest that IPAH is present from birth in some patients, although it is acquired later in life in others. The histopathologic changes have illustrated increased muscularity of the peripheral pulmonary arterioles, similar to IPAH.

## Bronchopulmonary Dysplasia and Pulmonary Hypertension

Bronchopulmonary dysplasia (BPD) is a chronic lung disease of infancy that occurs in premature infants after oxygen and ventilator therapy for acute respiratory failure at birth. When first characterized nearly 50 years ago, BPD was originally described as severe chronic respiratory disease with very high morbidity and high mortality in relatively late-gestation preterm infants, because infants below 28 weeks gestation rarely survived in that era.[40,41] With improved care in very premature infants in modern neonatal units, including gentle ventilation techniques, appropriate oxygenation and acid-base balance, nutrition, and other interventions, survival of infants beyond 23 weeks has dramatically improved. However, these successes have not led to a reduction in persistence of BPD, which remains a major problem, occurring in an estimated 10,000–15,000 infants per year in the United States alone, or in 68% of infants born at less than 29 weeks gestation and weighing less than 1500 g. In the previous era, BPD was related to airway injury, inflammation, and fibrosis due to ventilator damage and oxygen toxicity. The “new BPD” in the current era is characterized by impaired angiogenesis and alveolarization, with decreased vascular branching and persistent precapillary arteriovenous anastomotic vessels.[42–44] Despite the differences in the pathology and epidemiology of BPD over time, PH continues to contribute significantly to high morbidity and mortality and is present early in the course of disease. Even the original descriptions of BPD noted striking pulmonary hypertensive vascular remodeling in severe cases and that the presence of PH beyond 3 months of age was associated with high mortality. Now in the “postsurfactant era” or the “new BPD,” late PH continues to be strongly linked with poor survival, with reports suggesting mortality rates of greater than 50% for infants with severe PH.[45] Furthermore, the chronic lung disease can persist after infancy, with frequent hospitalizations due to respiratory problems in childhood and exercise limitations extending into adulthood.[46]

## Associated Pulmonary Arterial Hypertension With Congenital Heart Disease

PAH is an important determinant of morbidity and mortality in patients with CHD. An updated shunt-related classification (Table 35.1) was proposed at the fifth World Symposium on Pulmonary Hypertension in Nice, France (the Nice-CHD classification).[11,47] The value of this classification in determining survival of adult patients with CHD was recently described by Manes et al. and by Zijlstra in pediatric patients.[48] By definition, Nice group 1 includes ES, with reversal of a previous large shunt; group 2—hyperkinetic PAH with large left to right (L-R) shunts; group 3—PAH with coincidental CHD, which could not be causative to the PAH, such as small ventricular septal defects or atrial septal defects of <2 cm in size; and group 4—postoperative PAH with or without residual shunts.[47] PAH related to unrepaired CHD (i.e., ES) is thought to develop after exposure to hyperkinetic shear stress, following a period of normal PVR and increased pulmonary blood flow. Several types of congenital heart defect are associated with a greater risk for the development of pulmonary vascular disease. In patients with transposition of great arteries (TGA), truncus arteriosus, and atrioventricular canal (AVC) defects, pulmonary vascular changes are accelerated and seen in very early infancy. Repair should be performed in the neonatal period for TGA and truncus and in the first few months of life for AVC defects.[49–52] The progression of PH is also determined by coexisting genetic defects, including Down syndrome and other genetic syndromes, developmental lung disease, and metabolic and other systemic diseases. There is a whole group of patients with CHD-PAH who do not fit into the Nice-CHD classification, including segmental PH, as seen in aortopulmonary collaterals, patients with TGA after atrial switch surgery, and single ventricle physiology; the prognosis for these is variable.[22] The PVRI pediatric task force attempted to classify pediatric pulmonary hypertensive vascular disease into 10 categories, to try and include all of these issues; however, further large outcome studies are needed to validate the classification.[15] In children whose CHD is diagnosed later in life, one needs to determine whether the patient is “operable” or has “irreversible” pulmonary vascular disease. In the past, the evaluation of “operability” included anatomic criteria (Heath-Edwards classification) based on microscopic findings from lung biopsies to aid in the determination of “operability.” However, lung biopsies carry a significant risk of morbidity and mortality in this population. Furthermore, because the pulmonary vascular disease can be quite heterogeneous, a biopsy from one area of the lung may not necessarily represent the vascular disease in both lungs. Cardiac catheterization with acute vasoreactivity testing (AVT) is performed in children with CHD to assess whether the PVR will decrease sufficiently for surgical repair to be undertaken in borderline cases. The vast majority of children with CHD do not require cardiac catheterization as a prelude to repair. It is important to determine whether the elevated PVR index (PVRi) responds favorably to acute pharmacologic vasodilatation.[52] The availability of pulmonary vasodilators for the perioperative management of pulmonary hypertension have allowed for surgical “correction” in select patients who present later in life with borderline elevated PVRi in the range 3–5 Wood units × $m^2$. If a patient with elevated PVR is being considered for surgery, there is an increased risk of postoperative pulmonary hypertensive crises. Thus knowing if the pulmonary circulation will respond favorably to inhaled nitric oxide (NO) can help guide the management of this potentially life-threatening postoperative complication. In general, positive AVT for borderline cases with posttricuspid shunts is defined as a decrease in PVRi to <6–8 WU × $m^2$ or pulmonary vascular resistance/systemic vascular resistance (PVR/SVR) ratio <0.3.[14] However, AVT is only one measure used to define operability, and the whole clinical picture, the age of the patient, and the type of lesion should be taken into consideration. For patients with borderline elevated PVRi, partial or complete surgical closure may be attempted after treatment with targeted pulmonary vasodilators for a period of time and repeated hemodynamic studies. Partial closure of shunts may sometimes improve the clinical and hemodynamic status of such patients by reducing the shear damage with continued increased pulmonary blood flow from persistent shunts.

## Survival in APAH-CHD

Barst et al. compared patients with IPAH or HPAH ($n = 1{,}626$) to those with CHD-associated PAH ($n = 353$) who were enrolled in the REVEAL registry.[8,53] Of patients with CHD-associated PAH, 151 had ES. They showed that there was no significant survival rate at 4 and 7 years in patients with APAH-CHD (regardless of presence of a shunt) versus IPAH. Analysis of 240 patients with APAH-CHD enrolled in the Spanish registry (REHAP) revealed that within the group, patients with ES had better survival than postoperative PAH (which had outcomes similar to IPAH). Among ES, a pretricuspid shunt predicted worse survival.[12,54] Data from the German national register revealed 1-, 5-, and 10-year survival rates of 92, 75, and 57%, respectively, in the entire cohort of ES patients, with treatment-naïve patients having survival rates of 86, 60, and 34%, respectively.[55]

## Idiopathic/Heritable Pulmonary Arterial Hypertension

IPAH and HPAH, subtypes of PH group 1 PAH, are characterized by progressive pulmonary arterial vascular obliteration and subsequent right heart failure if untreated. A PAH patient is subclassified as having IPAH when a patient meets the hemodynamic criteria of PAH and all other associated forms of PAH (APAH) have been ruled out. HPAH previously referred to as FPAH occurs when there is a family history of PAH or identification of one of the genetic mutations associated with PAH, regardless of whether there is a family history or not. Although HPAH may represent a different clinical phenotype, both IPAH and HPAH likely represent overlapping diagnostic subgroups of PAH and are classified with other forms of PH group 1 PAH because of similar characteristics, histopathologic changes, and treatment responses.

## Epidemiology

The exact incidence and prevalence of IPAH/HPAH in children worldwide is unknown. Adult studies have reported an overall incidence of approximately 1–2 new IPAH cases per million in industrialized countries.[18,28,56,57] In the French and Scottish registries, the prevalence of group I PAH was reported as 15–50 PAH cases per million adults and included cases of APAH.[27] With respect to children, a national cohort study of IPAH children in the United Kingdom followed over 7 years reported a lower incidence and prevalence compared with adults.[58] The incidence of childhood IPAH was 0.48 cases per million children per year, and the prevalence was 2.1 cases per million. Of these patients, 7.8% had HPAH similar to reports in adults. The difference between the prevalence in the French registry and the UK childhood registry may be in part attributable to cases of PAH (including anorexigen related and CTD) included in the adult French registry that are not seen in children. A French pediatric registry reported a 4.4 per million prevalence of pediatric IPAH/HPAH.[24] However, this prevalence does not include APAH-CHD, a subgroup of PAH that is considered to make up at least 50% of pediatric PAH. Thus the “best” estimate for pediatric PAH prevalence is approximately 10 per million.

Although the disease is rare, with improved diagnostics and increased awareness, it appears that more patients (both children and adults) have PAH than was previously recognized. On occasion, infants who died with the presumed diagnosis of sudden infant death syndrome had IPAH diagnosed at postmortem examination. The female preponderance in adult patients with IPAH previously reported as approximately 1.7 : 1 females:males is similar to earlier reports in children with IPAH (i.e., 1.8 : 1), with no significant difference in younger children compared with older children.[59] More recent reports from the United States have reported a higher female preponderance in adults with PAH (i.e., approximately 4 : 1), with the gender ratio in the pediatric patients more similar to previous reports (i.e., approximately 2 : 1).

## Natural History

Historically, untreated IPAH exhibited a course of progressive right heart failure and early death. In contrast, patients with unrepaired CHD with shunts often lived for at least several decades without targeted treatment. Several large survival studies of primarily adult patients with IPAH were conducted in the 1980s prior to the current treatment era. These retrospective and prospective studies yielded quite uniform results: adult patients with IPAH who did not have lung or heart/lung transplantation had actuarial survival rates at 1, 3, and 5 years of 68%–77%, 40%–56%, and 22%–38%, respectively.[1] In the era before the use of continuous intravenous epoprostenol (approved in 1995), in children who were nonresponders to acute vasodilator testing and therefore not candidates for oral calcium channel blockade, the 1-, 3-, and 5-year survival rates were 66%, 52%, and 35%, respectively[3] In more recent times, with the use of epoprostenol treatment for nonresponders, and calcium channel blockade for responders, the 10-year survival for children was reported by Yung et al. at 78%.[53,60] However, there is significant biological variability in the natural history of the disease in both adults and children, with some patients having a rapidly progressive downhill course resulting in death within several weeks after diagnosis and others surviving for at least several decades.

## Pathogenesis and Pathobiology of Pediatric Pulmonary Arterial Hypertension

Although the exact mechanism of PAH development has not been completely elucidated, endothelial cell dysfunction with smooth muscle cell (SMC) proliferation, dysfunction, and altered apoptosis secondary to imbalance of vasoactive mediators is the most consistent common factor (Fig. 35.1).[61] A thorough understanding of the factors underlying the pathogenesis is the mainstay for developing targeted treatment modalities. As more and more factors involved in this complex process are uncovered, molecules targeting these individual pathways are concomitantly undergoing testing on animal and cellular models, giving rise to a whole new generation of medications recently added to the armamentarium available to clinicians.

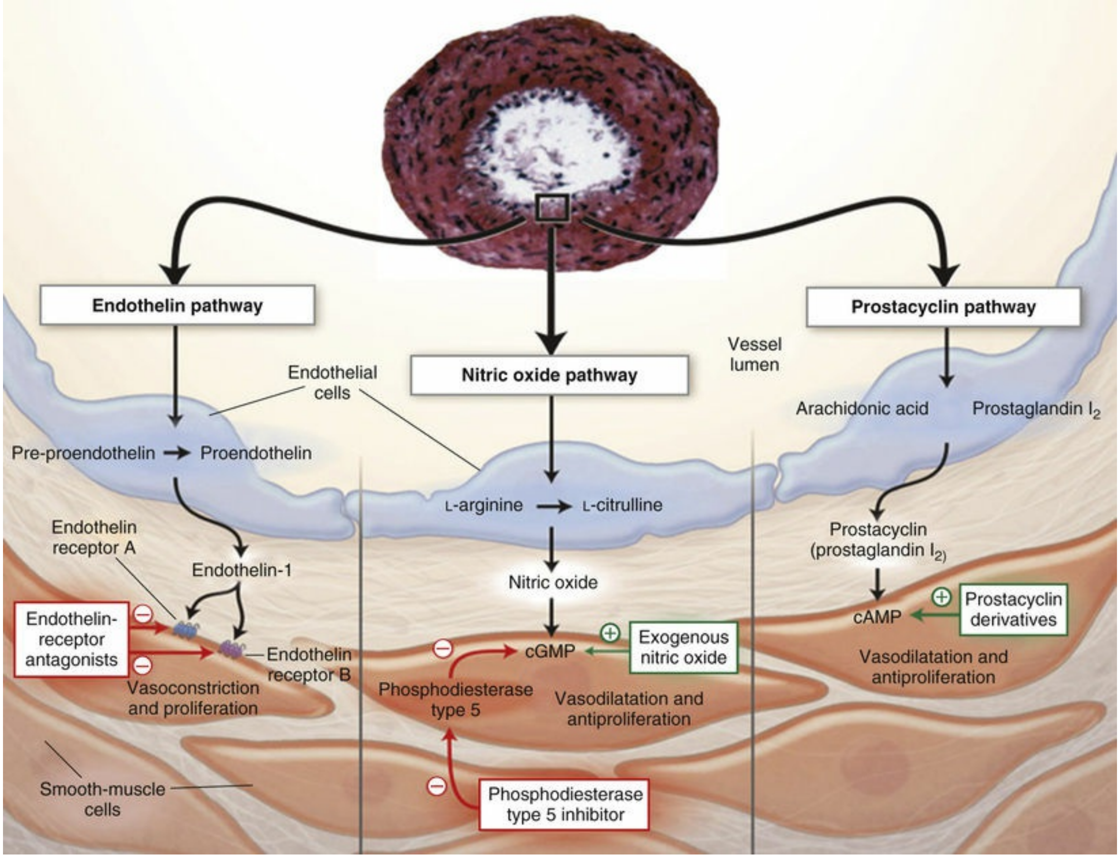
Pulmonary vascular disease is a multifactorial disease with several causes that lead to a final common histopathologic vasculopathy. Recent investigations in the basic science arena have uncovered several different biochemical/mechanistic features of pulmonary vascular obstructive disease that have led to novel treatments. These include abnormalities of the prostacyclin pathway, the endothelin (ET) system, and NO production/availability. Wagenvoort and Wagenvoort hypothesized that "PPH" (IPAH) afflicts individuals with hyperreactive pulmonary arterioles in whom various stimuli initiate vasoconstriction, with subsequent development of the characteristic vascular lesions.[62] Although the early focus for treatment of this disease stemmed from this hypothesis (i.e., finding the ideal pulmonary vasodilator), evidence over the past two decades has pointed to other vasoproliferative abnormalities. In infants, the pathobiology suggests failure of the neonatal vasculature to relax, in addition to a striking reduction in arterial number/surface area. However, with time, the changes become fixed, with a vasodilator-unresponsive component that appears temporally related to the development of thickened vascular media and adventitia with dramatic increases in the deposition of structural matrix proteins such as collagen and elastin in the pulmonary arterial wall.[63,64] In older children, intimal hyperplasia, occlusive changes, and plexiform lesions are found in the pulmonary arterioles. Despite significant advances in the understanding of the pathobiology of IPAH, the mechanisms that initiate and perpetuate this disease remain speculative. Adults with IPAH often have severe plexiform lesions and what appear to be "fixed" pulmonary vascular changes. In contrast, children with IPAH have more pulmonary vascular medial hypertrophy with less intimal fibrosis and fewer plexiform lesions. In the classic autopsy studies by Wagenvoort and Wagenvoort, medial hypertrophy was severe in patients younger than 15 years of age, and it was usually the only abnormality seen in infants. With increasing age, intimal fibrosis and plexiform lesions were seen more frequently. These postmortem studies suggested that pulmonary vasoconstriction, leading to medial hypertrophy, may occur early in the course of the disease and may precede the development of plexiform lesions and other fixed pulmonary vascular changes. The observations may offer clues to the observed differences in the natural history and factors influencing survival in children with IPAH compared with adult patients. In general, younger children appear to have a more reactive pulmonary vascular bed relative to both vasodilatation and vasoconstriction. Severe acute pulmonary hypertensive crises occur in response to pulmonary vasoconstrictor "triggers" more often in young children than in older children or adults. Based on these pathologic studies, the most widely proposed mechanism for IPAH until the late 1980s and early 1990s was pulmonary vasoconstriction.[65]

## Important Pathways Thought to Be Responsible for Vasoconstriction

The three important pathways that have been well studied are the prostacyclin pathway, NO pathway, and ET pathway (Fig. 35.2).[66]



Endothelin pathway
Nitric oxide pathway
Prostacyclin pathway

cGMP
Exogenous nitric oxide
Phosphodiesterase type 5
Vasodilatation and antiproliferation
Phosphodiesterase type 5 inhibitor
Arachidonic acid
Prostaglandin I2
Prostacyclin (prostaglandin I2)
cAMP
Prostacyclin derivatives
Vasodilatation and antiproliferation

**FIG. 35.2** Targets for current or emerging therapies in pulmonary arterial hypertension. Three major pathways involved in abnormal proliferation and contraction of the smooth muscle cells of the pulmonary artery in patients with pulmonary arterial hypertension are shown. These pathways correspond to important therapeutic targets in this condition and play a role in determining which of four classes of drugs—endothelin-receptor antagonists, nitric oxide, PDE5 inhibitors, and prostacyclin derivatives—will be used. At the top of the figure, a transverse section of a small pulmonary artery (<500 μm in diameter) from a patient with severe pulmonary arterial hypertension shows intimal proliferation and marked medial hypertrophy. Dysfunctional pulmonary artery endothelial cells *(blue)* have decreased production of prostacyclin and endogenous nitric oxide, with an increased production of endothelin-1—a condition promoting vasoconstriction and proliferation of smooth muscle cells in the pulmonary arteries *(red).* Current or emerging therapies interfere with specific targets in smooth muscle cells in the pulmonary arteries. In addition to their actions on smooth muscle cells,

prostacyclin derivatives and nitric oxide have several other properties, including antiplatelet effects. *Plus signs* denote an increase in the intracellular concentration; *minus signs* blockage of a receptor, inhibition of an enzyme, or a decrease in the intracellular concentration. *cAMP,* Cyclic adenosine monophosphate; *cGMP,* cyclic guanosine monophosphate; *PDE5,* phosphodiesterase 5. (From Wilkins MR. Pulmonary hypertension: The science behind the disease spectrum. *Eur Respir Rev*. 2012;21(123):19-26.)

1. Prostacyclin—PGI2, generated from arachidonic acid via the cyclooxygenase pathway, causes SMC relaxation and inhibits platelet aggregation via cyclic adenosine monophosphate (cAMP) production. Thromboxane (TX) synthetase, which is derived from the same substrate as PGI2 synthetase, generates $TXA_2$, which is a potent vasoconstrictor and leads to platelet aggregation. In IPAH the balance between PGI2 and $TXA_2$ is tilted in favor of the latter. Thus use of epoprostenol (PGI2) leads to pulmonary vasodilation and improvement in long-term outcomes by correcting this imbalance.
2. NO is synthesized in the endothelium by endothelial NO synthetase (eNOS). NO stimulates guanylate cyclase to produce cyclic guanosine monophosphate (cGMP), which has vasodilatory and antiproliferative properties. Identification of this pathway has led to the use of inhaled NO (iNO) therapeutically in the treatment of PAH, as well as development of other medications that lead to release of endothelial cGMP. In various forms of PAH, there is reduced bioavailability of eNO, either because of reduced eNOS expression or secondary to oxidative free radical production, which consumes NO. Asymmetric dimethyl arginine (ADMA) is elevated in many forms of PAH, and it acts either by inhibition of eNOS or via its direct effects on gene expression. Increased expression of the phosphodiesterase 5 (PDE5) enzyme also degrades cGMP and leads to vasoconstriction. PDE5 inhibitors replenish

cGMP and act as rescue agents, preventing rebound PAH when iNO is weaned off in patients, and also act as potent pulmonary vasodilators in various forms of PH.

3. The third pathway that has stirred a lot of interest in PAH research is the ET-1 pathway. ET-1 leads to vasoconstriction, fibrogenesis, and cell proliferation and acts via $ET_A$ and $ET_B$ receptors in the SMC. ET-1 levels are found to be increased in lung tissue and circulation in IPAH, APAH secondary to lung disease, and thromboembolism, as well as congenital diaphragmatic hernia patients. $ET_B$ receptors on endothelial cells are involved with release of eNO and PGI2; however, there seems to be no added advantage to selective $ET_A$ inhibition, suggesting that the relative expression of the two receptors in disease states may play a role.

Other vasoactive mediators at play are serotonin (5 hydroxytryptamine [5HT]), which is increased in patients with PAH and is a potent vasoconstrictor that causes remodeling. The roles of potassium and calcium channel function, caveolin, ADMA, and TNF$\alpha$ are all undergoing intense investigation.

## Endothelial Dysfunction

Endothelial dysfunction appears to be a key factor in mediating the structural changes that occur in the pulmonary vasculature in PAH. The integrity of the pulmonary vascular endothelium is critical for maintaining vascular tone, homeostasis, barrier function, leukocyte trafficking, transduction of luminal signals to abluminal vascular tissues, production of growth factors, and cell signaling with autocrine and paracrine effects.[67,68] In addition, abnormalities in vasoactive mediators appear to contribute to the pathobiology of PAH. Whether these perturbations are a cause or consequence of the disease process remains to be elucidated.

The vascular endothelium is now recognized as an important source of locally active mediators that contribute to the control of vasomotor tone and structural remodeling, and appears to play a crucial role in the pathogenesis of PAH. Various studies suggest that imbalances in the production or metabolism of vasoactive mediators produced in the lungs, as well as substances involving control of pulmonary vascular growth, may be important in the pathogenesis of PAH. These may include increased TX, ET, and serotonin, and decreased prostacyclin and NO, as well as changes in VEGF and xanthine oxidoreductase.[65,69] The endothelial cell dysfunction seen in association with PAH leads to the release of vasoproliferative substances in addition to vasoconstrictive agents that ultimately result in the progression of the pulmonary vascular remodeling and progressive vascular obstruction and obliteration. Stewart et al. and Giaid et al. reported elevated circulating levels of ET, a potent vasoconstrictor and mitogen, in patients with various forms of PAH and PH with increased local production of ET by the pulmonary arterial endothelium reported in the PAH patients.[63,70,71] Endothelial dysfunction also likely results in the release of chemotactic agents, leading to the migration of SMCs into the vascular wall, which may lead to the characteristic pulmonary arteriolar medial hypertrophy and hyperplasia. This endothelial dysfunction, coupled with the excessive release of locally active thrombogenic mediators, promotes a procoagulant state, leading to further vascular obstruction. Therefore the process is characterized by an inexorable cycle of endothelial dysfunction leading to the release of vasoconstrictive, vasoproliferative, and prothrombotic substances, ultimately progressing to vascular remodeling and progressive vascular obstruction and obliteration. Despite our lack of complete understanding of the pathogenesis of PAH, these imbalances and abnormalities have changed the focus of clinical drug development from chronic vasodilator therapy alone, to the evaluation of therapeutic agents that may reverse the vasoproliferation, and ultimately result in pulmonary vascular regression and reverse remodeling. Although various studies have demonstrated endothelial dysfunction in patients with PAH, whether the dysfunction is the primary problem or secondary to another insult remains unknown.

The theory that certain individuals are genetically susceptible has led to genetically oriented research. It is now clear that gene expression in pulmonary vascular cells responds to environmental factors, growth factors, receptors, signaling pathways, and genetic influences that can interact with each other. The molecular processes behind the complex vascular changes associated with PAH include phenotypic changes in endothelial and SMCs in hypertensive pulmonary arteries, the recognition that cell proliferation contributes to the structural changes associated with the initiation and progression of PAH, the role of matrix proteins and matrix turnover in vascular remodeling, and the importance of hemodynamic influences on the disease process. Examples of effector systems controlled by gene expression include transmembrane transporters, miRNA, ion channels, transcription factors, modulators of apoptosis, kinases, and cell-to-cell interactive factors, such as integrins, membrane receptors, growth factors, and cytokines.[32,38]

In addition, defects in the KCNK3s of pulmonary vascular SMCs may be involved in the initiation or progression of IPAH. Inhibition of the voltage regulated (Kv) KCNK3s in pulmonary artery SMCs taken from IPAH patients has been reported. Ma et al. described the association of a novel gene KCNK3 with HPAH.[38] Mutations of this gene reduced KCNK3 current, which has potential for developing a therapeutic target.

These studies suggest that IPAH is a disease of “predisposed” individuals, in whom various “stimuli” may initiate the pulmonary vascular disease process. By identifying molecular mechanisms that are linked to epidemiologic risk factors, as well as developing molecular, genetic, biochemical, and physiologic tests to monitor and diagnose IPAH, novel treatment strategies will improve therapeutic interventions for IPAH. There may be different subsets of patients in whom vasoconstriction is the predominant feature, and those in whom vascular injury or endothelial dysfunction is the primary problem. Even so, these components appear closely intertwined. Whether these physiologic processes (vasoconstriction vs. vascular injury) are a cause or a consequence of the disease remains unclear.

## Cell Proliferation and Apoptosis

Many of the mediators described previously also play an important role in cell proliferation and remodeling in addition to vasoconstriction. Abnormalities in signaling pathways lead to impairment of apoptosis and increase in proliferation. Both endothelial and SMCs in patients with PAH demonstrate mitochondrial abnormalities, which lead to a shift in metabolism favoring glycolysis for ATP generation and possibly altering the apoptosis potential. Mutations in BMPR2 ALK-1 and ENG lead to vascular remodeling and are potential pathways for therapeutic intervention. When loss of BMPR2 is experimentally induced, PA endothelial cells and SMCs are more susceptible to apoptosis, migration, and proliferation in response to TGFβ1.[72]

## Growth Factors

Several growth factors act as potent mitogens and chemotactic agents in PAH. Increased vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF) levels have been recorded in various forms of PAH, including neonatal PPHN. Other growth factors, including TNF$\alpha$ and platelet-derived growth factor (PGDF), are also implicated in PAH. Most of these growth factors act by activating tyrosine kinase receptors, which initiates major signaling cascades within the cells, resulting in an antiapoptotic and proproliferative phenotype. Human trials using tyrosine kinase inhibitors are ongoing, with promising results in selected patient groups with PAH. Peroxisome proliferator activated receptor $\gamma$ (PPAR $\gamma$) expression is reduced in endothelial cells of plexiform lesions in PAH patients. This is important for BMP2-mediated inhibition of SMC proliferation and reduces ET-1 levels.

## Apoptosis

The plexiform lesion forms a fascinating substrate for studying the mechanism of vascular proliferation and remodeling. Selective apoptosis of endothelial cells results in unbridled proliferation of apoptosis-resistant precursor cells driven by changes in BMPR2, mitochondrial metabolism, altered signaling factors (Notch-3), TK activation, and potassium and Ca channel derangements. This process also requires activation of prosurvival transcription factors linked to development of PAH. Abnormalities in proteases and elastases are also implicated in abnormal lung remodeling.

## Inflammation and Thrombosis

Inflammation has long been implicated to play a triggering role in PAH, as evidenced by an increase in cytokines, interleukins, and chemokines, especially in PAH crisis.[73–76] Endothelial dysfunction and inflammation predispose to *in situ* thrombosis in PH. Patients with IPAH have increased von Willebrand factor levels and also have increased platelet aggregation and a hypercoagulable state. Use of anticoagulants has been shown to reduce the incidence of thrombosis both in IPAH and chronic thromboembolic pulmonary hypertension (CTEPH).

## Pathophysiology

Although the histopathology and pathobiology in children with IPAH is similar to that seen in adult patients, there may be differences in the pathophysiology that alter the clinical presentation, natural history, and outcome in children. For example, children appear to have differences in their hemodynamic parameters at the time of diagnosis compared with adult patients.[59] Children with IPAH most often have a normal cardiac index at the time of presentation, as opposed to adults who frequently present in clinical right heart failure with a low cardiac index. This may reflect earlier diagnosis and explain why children tend to have a greater response rate to acute vasodilator testing than adults.

A brief review of the normal physiology of the pulmonary circulation will enable a better understanding of the pathophysiology of the pulmonary vascular bed.[77,78] The normal fall in PVR occurs soon after birth and reaches normal adult levels by 4–6 weeks of life. The normal pulmonary vascular bed is a low pressure, low resistance, highly distensible system that can accommodate large increases in pulmonary blood flow with minimal elevations in pulmonary arterial pressure (PAP). In PAH, however, this capacity to accommodate increases in pulmonary blood flow is lost due to the increase in PVR, leading to increases in pulmonary artery pressure at rest and further elevations in pulmonary artery pressure with exercise. The right ventricle hypertrophies in response to this increase in afterload. If there has been a gradual exposure over time, the right ventricle has the ability to remodel and adapt to the pressure overload by recruitment of sarcomeres and hypertrophy of myocytes. The adaptation of the right ventricle to increased afterload, such as in IPAH or congenital heart defects with increased right ventricular afterload (e.g., pulmonic stenosis), is a double-edged sword. The right ventricular hypertrophy will assist the right ventricle in pumping against the increased afterload; however, this occurs at a cost to left ventricular integrity. Under normal conditions, the right ventricle is crescent shaped with the right ventricular free wall and interventricular septum concave around the left ventricle at both end diastole and end systole. During systole, the left ventricle contracts toward a central axis, while the right ventricular free wall and septum contract in parallel. With right ventricular hypertrophy, the interventricular septal orientation flattens and ultimately commits to the right ventricle in severe cases. This may lead to a vicious cycle of left ventricular diastolic dysfunction and subsequent worsening of right heart failure in severe cases.[79–81] In the early stages the right ventricle is capable of sustaining normal cardiac output at rest, but the ability to increase cardiac output with exercise is impaired. As pulmonary vascular disease progresses, the right ventricle fails and resting cardiac output decreases. As right ventricular dysfunction progresses, right ventricular diastolic pressure increases with clinical onset of right ventricular failure, the most ominous sign of pulmonary vascular disease. Dyspnea is the most frequent presenting complaint in adults and children with IPAH; it is due to impaired oxygen delivery during physical activity as a result of an inability to increase cardiac output in the presence of increased oxygen demands. Syncopal episodes, which occur more frequently with children than with adults, are often exertional or postexertional and imply a severely limited cardiac output, leading to a decrease in cerebral blood flow. Peripheral vasodilatation during physical exertion can exacerbate this condition. However, syncope may also reflect a very vasoactive circulation with rapid changes in the pulmonary vascular reactivity in response to various stimuli.

The two most frequent mechanisms of death in PAH are progressive right ventricular failure and sudden death, with the former occurring more often, especially in adults. Progressive right ventricular failure leads to dyspnea and a progressive decrease in cardiac output.[8] Complicating illnesses such as pneumonia can be fatal because alveolar hypoxia causes hypoxic pulmonary vasoconstriction, leading to an inability to maintain adequate cardiac output, which results in cardiogenic shock and death. When arterial hypoxemia and acidosis (respiratory or metabolic) occur, life-threatening arrhythmias may develop. Postulated mechanisms for sudden death include bradyarrhythmias and tachyarrhythmias, acute pulmonary emboli, acute pulmonary artery aneurysm rupture, massive pulmonary hemorrhage, and sudden right ventricular ischemia. Hemoptysis appears to be due to pulmonary infarcts from secondary arterial thromboses.

## Clinical Presentation

The clinical presentation of pediatric pulmonary hypertension is often indistinguishable from other chronic cardiorespiratory diseases. Specific neonatal conditions such as PPHN and BPD-PH or congenital diaphragmatic hernia with PH have signs and symptoms attributable to the causative condition.

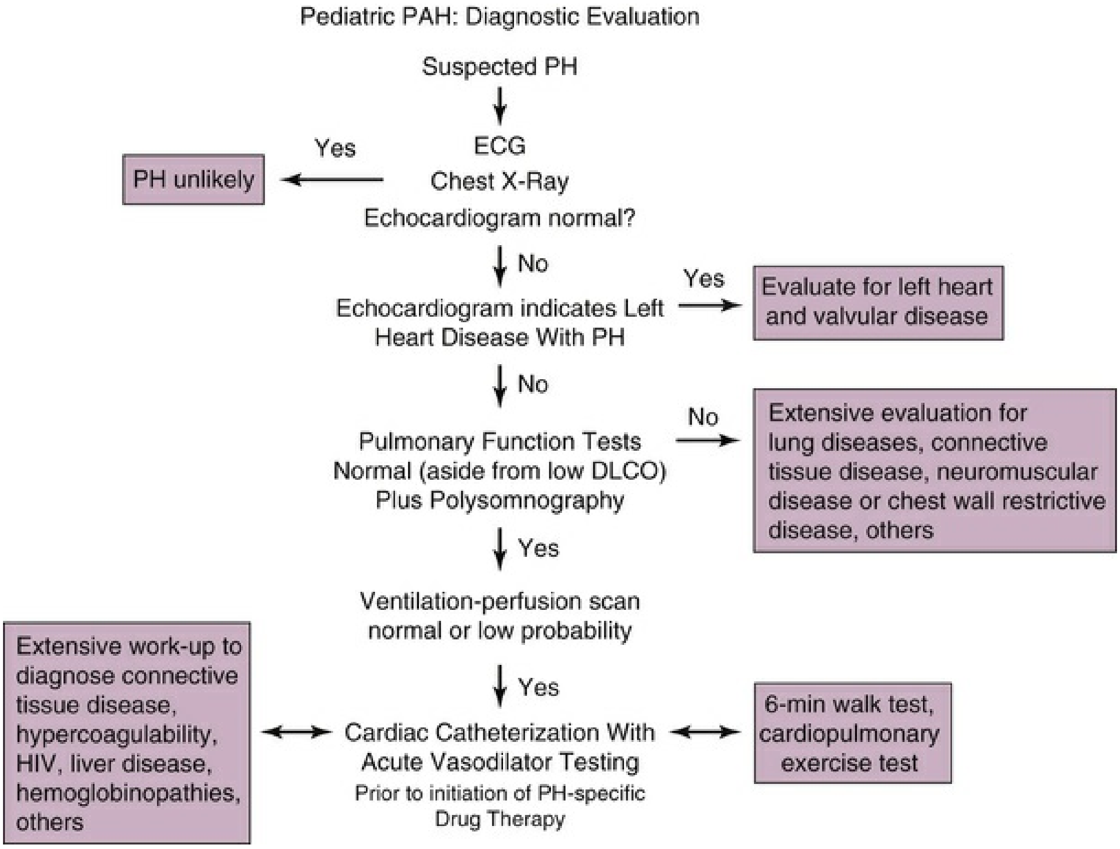
Data from 216 children enrolled in the REVEAL registry showed that the median age at PAH diagnosis was 7 years, and the most frequent presenting symptoms were exertional dyspnea, seen in 53% of IPAH and 30% in CHD-PAH, and fatigue in 25% and 21% in the two groups.[3,59,82] Effort intolerance arises from the inability of the cardiac output to increase appropriately to the oxygen demands from effort in these children. In children with CHD-PAH, fatigue and exertional dyspnea may be underreported because of these patients adapting their lifestyle to a more sedentary one, because of long-standing disease. Presyncope/syncope was present in 36% of IPAH and only 4% of CHD-PAH, possibly reflecting the effect of having a shunt to pop off during PH crisis. Syncopal episodes, which occur more frequently with children than with adults, are often exertional or postexertional and imply a severely limited cardiac output, leading to diminished cerebral blood flow.[29,83] Peripheral vasodilatation during physical exertion can exacerbate this condition. In the TOPP registry, syncope was noted to be twice as common in children (25% vs. 12%) and is often the presenting symptom.[29] Syncope occurs because of the acute drop in left ventricular output with the ventricular septum bowing into the left ventricle, restricting its stroke volume and ejection fraction. In patients with shunts, PH crisis is associated with a greater right to left shunting, thereby maintaining left ventricular output at the cost of oxygen saturation. Thus, rather than syncope, these children present with increased cyanosis and an increased oxygen requirement at the time of PH crisis. Cyanosis is commonly seen in patients with right to left shunts at baseline or shunts that reverse with exertion due to increased RV work. In IPAH, cyanosis occurs in the presence of an atrial shunt. With increasing cyanosis in ES patients comes the risk of increasing hematocrit with all the side effects of polycythemia, including headaches, coagulopathies, and microthrombosis. Hemoptysis can occur secondary to pulmonary infarcts with secondary arterial thrombosis; in patients with HHT, due to pulmonary telangiectasia; and, in some patients, because of overzealous or unsupervised anticoagulation. Chest pain was described in 16% of IPAH as compared with 3% of ES patients and is likely from right ventricular endothelial ischemia. Dilated pulmonary arteries compressing the coronary circulation have also been described to cause acute angina. A small proportion of patients, 3% and 7%, reported no symptoms in the two groups. In infants with PAH, failure to thrive is another significant symptom, in addition to those attributed to right heart failure, including irritability, feed intolerance, pedal and sacral edema, and malabsorption from intestinal edema. Patients with portopulmonary hypertension, metabolic disorders, and hematologic diseases and those with CTD associated PAH will exhibit symptoms related to the primary disease conditions.[84,85] The two most frequent mechanisms of death are progressive right ventricular failure and sudden death. Comorbidities such as pneumonia and other systemic infections result in alveolar hypoxia, leading to a downward spiral of pulmonary vasoconstriction and compromised cardiac output, resulting in cardiogenic shock and death. In addition to right ventricle hypertrophy (RVH) and right ventricle (RV) dilatation, elevated RV end diastolic pressures lead to right atrial dilatation and atrial arrhythmias, including atrial fibrillation and ventricular arrhythmias. Acidosis can make the arrhythmias worse, and the loss of atrial kick in atrial fibrillation and flutter can lead to low cardiac output and death. Possible mechanisms for sudden death include ventricular arrhythmias, acute pulmonary emboli, massive pulmonary hemorrhage, sudden right ventricular ischemia, and acute increases in RV pressure, leading to posterior septal bowing into the left ventricle and an acute drop in cardiac output.

## Physical Examination Findings

Failure to thrive, with reduced height and weight percentiles, is often present, and is an indicator of chronic disease. APAH with other diseases such as scleroderma or lupus will have the skin and joint manifestations of the primary disease. Genetic syndromes associated with PH, such as trisomies, CHARGE syndrome, Dursen syndrome, glycogen storage diseases, and other metabolic disorders, all have specific phenotypes.[36,86] Signs of heart failure, including tachycardia, tachypnea, edema, and hepatosplenomegaly, may be present. Hypotension is often associated with PH crises and is associated with a grave prognosis. Cardiac examination in children with IPAH may reveal a right ventricular heave, a loud pulmonary component of the second sound, a pulmonary artery systolic click, the holosystolic murmur of tricuspid regurgitation (TR), a right ventricular gallop, and a prominent early diastolic murmur of pulmonary regurgitation (PR). In CHD-PAH the cardiac findings will depend on the underlying heart disease. Clubbing and cyanosis are usually associated with ES. Unless there is associated lung disease or pleural effusions from heart failure, the lung exam should be normal.

## Diagnosis and Assessment

It is important that the diagnosis and evaluation of children with suspected PH be done at a specialty center with expertise in the management of PH.[87] An algorithm illustrating the diagnostic workup for pediatric PAH is shown in Fig. 35.3. The diagnosis of IPAH is one of exclusion. It is critical to exclude all likely related or associated conditions that might be managed differently. A detailed history and physical examination, as well as appropriate tests, must be performed to uncover potential causative or contributing factors, as well as to assess cardiac function and functional class of the patient at baseline. A detailed family history, including a diagnosis of pulmonary hypertension, connective tissue or rheumatologic/immune disorders, CHD, other congenital anomalies, and unexplained deaths, may be contributory. If the family history suggests FPAH, careful screening of all first-degree relatives is recommended. Genetic testing should ideally be performed in all patients presenting with PH. Additional issues to address include obtaining a detailed birth/neonatal history, a medication history, exposure to high altitude or to toxic cooking oil, travel history, and any history of frequent respiratory tract infections, or venous or arterial thrombi.[88] The medication history should also include psychotropic drugs; appetite suppressants; chemotherapy, including tyrosine kinase inhibitors (dasatinib); use of glucagon in infants; selective serotonin reuptake inhibitors (SSRIs) in pregnancy; and over-the-counter drugs. The answers to these questions may offer clues to a possible "trigger" for the development of the PAH.



Pediatric PAH: Diagnostic Evaluation
Suspected PH
ECG
Chest X-Ray
Echocardiogram normal?
Yes
PH unlikely
No
Echocardiogram indicates Left Heart Disease With PH
Yes
Evaluate for left heart and valvular disease
No
Pulmonary Function Tests Normal (aside from low DLCO) Plus Polysomnography
No
Extensive evaluation for lung diseases, connective tissue disease, neuromuscular disease or chest wall restrictive disease, others
Yes
Ventilation-perfusion scan normal or low probability
Yes
Cardiac Catheterization With Acute Vasodilator Testing
Prior to initiation of PH-specific Drug Therapy
Extensive work-up to diagnose connective tissue disease, hypercoagulability, HIV, liver disease, hemoglobinopathies, others
6-min walk test, cardiopulmonary exercise test

**FIG. 35.3** Algorithm illustrating general diagnostic

workup for pediatric pulmonary arterial hypertension. *DLCO,* Diffusing capacity of the lungs for carbon monoxide; *ECG,* electrocardiogram; *HIV,* human immunodeficiency virus; *PH,* pulmonary hypertension.

(From Abman SH, Hansmann G, Archer SL, et al. Pediatric pulmonary hypertension: guidelines from the American Heart Association and American Thoracic Society. *Circulation*. 2015;132(21):2037-2099.)

The diagnostic evaluation in children suspected of having PAH is similar to that of adult patients. Follow-up evaluations are done 3–6 monthly to assess detailed functional class, both on history as well as testing, which should include a 6-minute walk test, cardiopulmonary exercise testing (CPET), imaging studies, and laboratory testing.

## Echocardiography in Pediatric Pulmonary Arterial Hypertension

Echocardiography has a very important role to play in the diagnosis and follow-up of patients with PAH. It is used to screen for PH, rule out associated structural heart disease, determine heart function, and estimate the PAP by Doppler.[89,90]

The echo protocol suggested for an IPAH patient includes two-dimensional (2D) and Doppler evaluation for atrial and ventricular enlargement and hypertrophy. Pulmonary artery systolic pressure (PASP) can be determined by measuring the peak systolic pressure gradient from the right ventricle to the right atrium (calculated using the Bernoulli equation $P = 4v$ [2], where $v$ is the maximum velocity of the TR jet measured by continuous wave Doppler) and adding the estimated right atrial pressure. The TR jet may be inadequate to estimate peak velocity in 10%–25% of patients, and simultaneous systemic blood pressure (BP) should be measured and documented in all studies. Using the TR jet velocity (TRV) as an estimate of PASP can overestimate or underestimate the PAP, and the clinician uses other features of the echocardiogram to support the diagnosis.[90–93] Adult studies estimate the sensitivity and specificity of TRV Doppler to be 0.79–1 and 0.68–98, respectively, but it is lower in infants with lung disease. Estimation of RV function is challenging due to the complex geometry of the RV compared with the left. Several measures have been described to estimate the degree of RV dysfunction, including the Tei index, (myocardial performance index), tissue Doppler, RV ejection fraction, RV fractional area change, and tricuspid annular plane systolic excursion (TAPSE).[94] The pulmonary artery Doppler also provides helpful clues toward indirect estimation of PVR.[92] Prolongation of the PA preejection time suggests elevated PVR. Shortened PA acceleration time and presence of systolic notching on PA Doppler suggest elevated PVR. When PR is present, the velocity profile of the pulmonary regurgitant jet can be used to estimate the pulmonary artery diastolic pressure. The peak PR and the end diastolic PR gradients correlate with mean and end diastolic PA pressures. In the presence of ventricular or great artery level shunts, the Doppler gradient across the shunts can give an estimate of RV and PA systolic pressures. Ventricular septal flattening and posterior systolic bowing occur as the right ventricular pressure increases and then exceeds the left ventricular pressure. The ratio of the left ventricle (LV) minor and major axes in the parasternal short axis view at the level of mitral valve chordae is the eccentricity index, which quantifies septal flattening and RV-LV interactions. With severe right ventricular hypertension, as the septum bows posteriorly pancaking the LV, the LV size and diastolic filling is reduced, and hence LV diastolic function gets compromised. The LV systolic function is usually preserved at this time. A redistribution of left ventricular filling from early to late diastole as demonstrated by Doppler reflects reduced compliance.[91,92,95,96] Diastolic dysfunction of the ventricles can be quantified by mitral and tricuspid diastolic inflow velocities, pulmonary and systemic venous flow patterns, and tissue Doppler imaging of the mitral and tricuspid annulus.

## Hemodynamics/Cardiac Catheterization

Despite advances in noninvasive technology, cardiac catheterization remains the “gold standard” for the diagnosis of PAH. Cardiac catheterization is necessary (1) to confirm the diagnosis and assess the severity of PH; (2) to exclude other potentially treatable conditions, such as pulmonary thromboembolic disease; (3) to rule out left heart disease; (4) to assess response to vasodilators before starting therapy (and to reassess on therapy to determine need for escalation or change in treatment); (5) to determine operability in patients with APAH-CHD; and (6) to determine suitability for lung transplantation. Cardiac catheterization is performed under general anesthesia or conscious sedation. It is important that the procedure is performed at centers with multispecialty experience in management of PH, as there can be significant morbidity and mortality. In experienced hands the risk of complications is 0%–1%.[97–101] As shown in the diagnostic algorithm (see Fig. 35.3), all children should undergo a diagnostic cardiac catheterization with acute pulmonary vasodilator testing using a short-acting vasodilator to determine acute vascular responsiveness.[14] In very small premature infants with PH or in critically ill children presenting with severe PH in heart failure, treatment may be initiated with prostanoids or other appropriate targeted therapy prior to cardiac catheterization, which is then performed when the patient is a more suitable candidate from a size and stability standpoint. The younger the child is at the time of diagnosis, the more likely that the child will respond to acute testing, but there is wide variability. The presence of a robust response to acute vasodilator testing usually predicts long-term response to high-dose oral calcium channel blockade therapy. Unfortunately there are no additional hemodynamic or demographic variables that accurately predict whether or not a child will respond to acute vasodilator testing. It appears that HPAH patients are less likely to respond to acute vasodilator testing and therefore less likely to respond to chronic calcium channel blockade treatment. Acute vasoreactivity has been defined differently by different authors. In adults, the most accepted definition is the Sitbon criteria: reduction in mean PAP by at least 10 mm Hg to <40 mm Hg, with no change or increase in the cardiac index.[102] The REVEAL registry used the modified pediatric criteria of a decrease in mPAP >20%, with an increase or no change in the cardiac index and a decrease or no change in the PVR/SVR ratio, to analyze their pediatric subgroup.[82] They found 35% of their IPAH (36/102 patients of which 5/13 were HPAH) and 15% of their APAH (9/60) were acute responders. When the Sitbon criteria were used, this proportion dropped to 19% of IPAH and 7% of APAH-CHD patients, which is similar to adult values. The REVEAL registry analyzed 5-year survival based on the pediatric criteria and found no death in the 22 acute responders who were treated with calcium channel blockers, in the 5 years following diagnostic right heart catheterization.[8] These observations underscore the marked biological variability in the time course of IPAH and emphasize the need to individualize the therapeutic approach. The currently recommended vasodilators for acute vasodilator drug testing are iNO (20–80 PPM), 100% oxygen, inhaled iloprost, intravenous epoprostenol, intravenous adenosine, and intravenous sildenafil. Patients who do not manifest a response to acute vasodilator testing are unlikely to have clinical benefit from chronic oral calcium channel blockade therapy. Furthermore, acute deterioration and decompensation may occur with empiric calcium channel blockade therapy in patients who are not acutely responsive, particularly in children with underlying lung disease. Patients with veno-occlusive disease or WHO group 2 PH may develop acute pulmonary edema during vasodilator testing and require very close monitoring if testing is done. Cardiac catheterization is also essential in patients with APAH-CHD to evaluate shunts and determine operability, as well as response to therapy. Left heart catheterization is done to assess pulmonary venous, left atrial, and left ventricular pressures and to evaluate for covert or overt diastolic dysfunction, and angiograms are performed to evaluate for aortopulmonary collaterals, pulmonary vein stenosis, and peripheral pulmonary artery stenosis or occlusion with thrombus. Cardiac catheterization is repeated in the setting of clinical worsening on therapy, after a change in therapy, or every 1–2 years during follow-up to assess continued response to therapy (AHA guidelines).

Other imaging studies include computerized tomography (CT) scans to evaluate parenchymal lung disease and vascular lesions, and CT angiograms to help in diagnosing pulmonary venous and arterial abnormalities, as well as to detect pulmonary embolism.[103–105] Ventilation-perfusion scans are performed in older children to diagnose pulmonary embolism and also to evaluate differential blood flows in children with PH after surgery for CHD.

## Magnetic Resonance Imaging

Because the shape of the right ventricle limits the ability of echocardiography to accurately assess RV volume, mass, and function, magnetic resonance imaging (MRI) has become the gold standard for evaluating the RV. It is particularly useful in serial follow-up after surgery. In young children, MRI still requires sedation to ensure adequate imaging, and this may be an added risk factor in children with PAH. However, in adults with PAH, indices of ventricular size and function are useful in predicting mortality, and the use of MRI is more widespread.[98,106,107]

## Assessment of Functional Capacity

### The 6-Minute Walk Distance (6MWD) Test.

This is used in children older than 6–8 years, who are capable of performing an adequate 6MWD, for baseline assessment and serial follow-up on therapy. It is a useful test to follow patients on therapy; however, in pediatrics, one must take into account age, height, and weight while interpreting the results, and its utility has not been well-validated in children.

### Cardiopulmonary Exercise Testing.

This test is performed in children older than 7–8 years, who are capable of using a bicycle ergometer. Variables measured include maximal oxygen consumption, carbon dioxide elimination, cardiac output, and anaerobic threshold. Yetman et al. reported in a series of 40 children with PAH who underwent CPET that parameters such as peak oxygen consumption ($pV\text{O}_2$), anaerobic threshold, end tidal carbon dioxide, and change in ventilation per amount of expired carbon dioxide ($VE/V\text{CO}_2$) correlated with invasive measures of disease severity, including pulmonary vascular resistance.[108–111]

### Laboratory Testing.

Baseline and follow-up laboratory testing performed include the following: (1) Those required to diagnose etiology of disease include hematologic tests for coagulopathy, factor V Leiden abnormalities, hemoglobinopathies, and connective tissue disorders. (2) Monitoring effects of treatment includes complete blood counts, liver function tests, and thyroid function tests. (Anemia and elevated aminotransferases may be caused by ET receptor antagonists, low platelets may be a marker for worsening PH, and thyroid dysfunction is a side effect of prostanoids.) (3) Biomarkers for ventricular function are brain natriuretic peptide (BNP) and N-terminal pro B-type natriuretic peptide (NT-proBNP), which are useful in following improvement or worsening of PH in response to therapy.[112,113] Circulating endothelial cells have been described by Levy et al. from Paris as another biomarker to assess severity of PH and response to therapy.[70,114,115] (4) Genetic tests, including BMPR2, ALK1, ENG, SMAD, KNCK3, ELF2AK4, and Cav1, should ideally be performed in all patients at the time of initial evaluation, especially in children with FPAH.

A sleep study is recommended in patients at risk for sleep-disordered breathing, including children with genetic syndromes, former preterm infants, obese children, and those who do not respond appropriately to targeted therapy.[116]

# Management

Although there is no cure for PAH, nor a single therapeutic approach that is uniformly successful, therapy has dramatically improved over the past several decades, resulting in sustained clinical and hemodynamic improvement, as well as increased survival in many children with various types of PAH.[58,117] An overview of our current approach and guidelines for treatment is shown in Fig. 35.3. Noninvasive studies obtained prior to initiating therapy, as well as periodically thereafter, are useful in guiding changes in therapeutic regimens, particularly in light of advances with various novel therapeutic agents.

## General Measures

The pediatrician plays an invaluable role in the care of children with PAH. Because children often have a more reactive pulmonary vascular bed than adult patients, any respiratory tract infection that results in ventilation/perfusion mismatching from alveolar hypoxia can result in a serious or even catastrophic acute pulmonary hypertensive crisis if not treated aggressively. Influenza and pneumococcal vaccinations are recommended unless there are contraindications. Antipyretics should be administered for temperature elevations greater than 101° F (38° C) to minimize the consequences of increased metabolic demands on an already compromised cardiorespiratory system. Children may also require aggressive therapy (e.g., iNO) for acute pulmonary hypertensive crises occurring during episodes of pneumonia or other infectious diseases. Patients may require antitussive medications during upper respiratory infections to prevent excessive coughing, which increases pulmonary artery pressures and can result in acute pulmonary hypertensive crises. Decongestants with pseudoephedrine should be avoided because they may exacerbate the pulmonary hypertension. Diet and medical therapy should be used to prevent constipation because Valsalva maneuvers transiently decrease venous return to the right side of the heart and may precipitate syncopal episodes.

## Anticoagulation

Consideration of chronic anticoagulation in children with PAH is based on observational studies in adults with IPAH.[118] The lung histopathology often demonstrates thrombotic lesions in small pulmonary arterioles in both adult and pediatric patients with IPAH and other forms of APAH. Some patients have an underlying coagulopathy (e.g., antiphospholipid syndrome or protein C/S deficiency). In patients with poor right ventricular function, thrombi can form within the ventricle, and postmortem examinations of patients with pulmonary vascular disease who have died suddenly often demonstrate fresh clot in the pulmonary vascular bed. Whether or not secondary thrombosis *in situ* is a significant exacerbating factor in patients with a normal resting cardiac output is unknown. In addition, even a small pulmonary embolus can be life-threatening in patients who cannot vasodilate or recruit additional pulmonary vessels. Clinical data supporting the chronic use of anticoagulation are limited.[119,120] Warfarin has been shown to be associated with improved survival in two retrospective adult observational studies, and one prospective adult observational study (in patients who were not responsive to acute vasodilator testing); all three studies were in adult patients with IPAH/HPAH or PAH associated with anorexigen exposure. The dosage of anticoagulation usually recommended is that to achieve an international normalized ratio (INR) of 1.5–2; however, certain clinical circumstances (e.g., positive lupus anticoagulant, positive anticardiolipin antibodies, factor V Leiden, factor II 20210A variant, and documented chronic thromboembolic disease) may require dose adjustment to maintain a higher INR. For patients at a higher risk of bleeding (e.g., patients with significant thrombocytopenia), the dosage should be adjusted to maintain a lower INR. Whether or not chronic anticoagulation is efficacious and safe for children with pulmonary hypertension remains to be determined. The guidelines suggest anticoagulation in older children who are hypercoagulable or in right heart failure, similar to the approach for adult patients.[14] In children who are extremely active, particularly toddlers, anticoagulation can be risky and not routinely recommended, unless there is a proven coagulation disorder. Antiplatelet therapy with aspirin or dipyridamole does not appear to be effective in areas of low flow, where thrombosis *in situ* is known to occur. However, studies have not been done to evaluate such agents in PAH. Parents should be advised to avoid administering other medications that could interact with the warfarin unless the possible interactions are known, and the dose of the warfarin is adjusted as needed. Similar to the approach with adult pulmonary hypertension patients, if anticoagulation with warfarin is contraindicated or dose adjustments are difficult, low-molecular-weight heparin at a dose of 0.75–1 mg/kg by subcutaneous administration once or twice daily may be a reasonable alternative. However, the long-term side effects of heparin, such as osteopenia and thrombocytopenia, are of concern. To date there are no studies comparing the safety and efficacy of anticoagulation with warfarin to heparin. There may be additional benefits of heparin on the pulmonary vascular bed.

## Calcium Channel Blockade

Calcium channel blockers are a chemically heterogeneous group of compounds that inhibit calcium influx through the slow channel into cardiac and SMCs. Their usefulness for select patients with PAH is based on their pulmonary vasodilator effects. Acute vasodilator testing during right heart catheterization is a critical part of the initial assessment of patients with PAH to determine the appropriate initial treatment course. Chronic calcium channel blockade is efficacious for patients ("responders") who demonstrate a robust acute response to vasodilator testing, although not all acute "responders" have a sustained long-term response.[5,102,121] In contrast, patients who do not respond acutely fail to respond to long-term calcium channel blockade. In general, these "nonresponders" will respond to long-term treatment with an intravenous prostacyclin, such as epoprostenol, and may respond to other novel treatments. The term "nonresponder" is only used with respect to acute vasodilator testing and calcium channel blockade response.

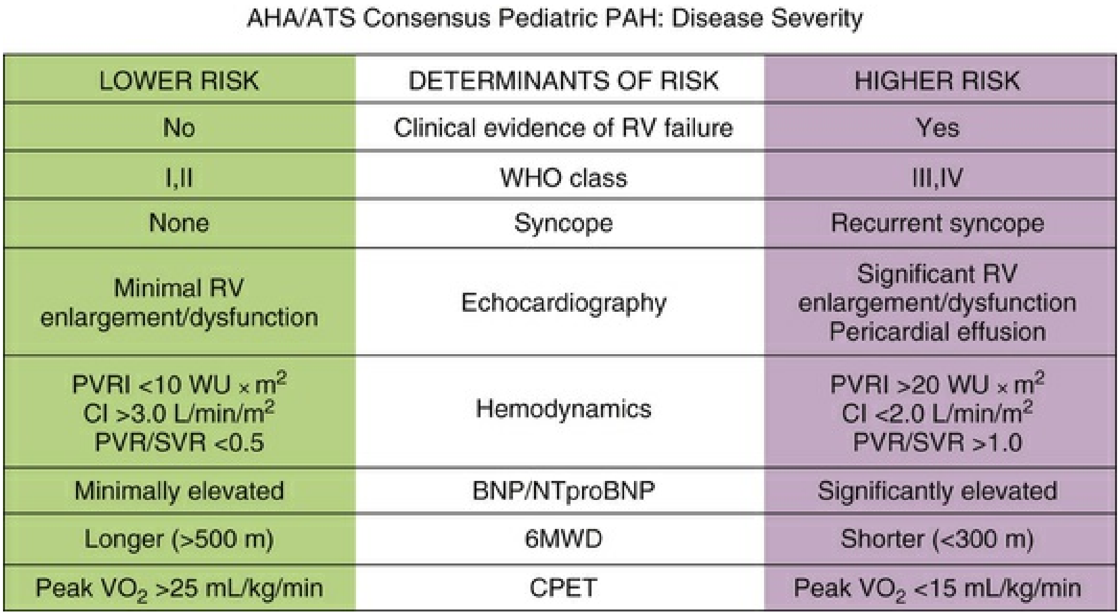
For acute responders, most adult studies have used calcium channel blockers at relatively high doses (e.g., long-acting nifedipine 120–240 mg daily or amlodipine 2.5–10 mg daily), with lower doses appropriate to weight in children. Calcium channel blockers are also not recommended in infants.[14] Because of the frequent occurrence of significant adverse effects with calcium channel blockade therapy in nonresponders, including systemic hypotension, pulmonary edema, right ventricular failure, and death, treatment with calcium channel blockers is not recommended for patients in whom acute effectiveness has not been demonstrated. This supports the importance of an initial assessment by cardiac catheterization with acute vasodilator testing before prescribing a long-term pulmonary vasodilator.

## Serial Reevaluations

Serial reevaluations, including repeat vasodilator testing to maintain an "optimal" chronic therapeutic regimen, are essential to the care of children with PAH. In our experience, acute "responders" who are treated with chronic oral calcium channel blockade therapy continue to do exceedingly well as long as they remain acutely reactive to vasodilator testing on repeat cardiac catheterizations. In contrast, children who are initially acute "responders" and are treated with chronic calcium channel blockade, and who then stop demonstrating active vasoreactivity on repeat testing, usually deteriorate clinically and hemodynamically despite continuation of chronic calcium channel blockade therapy. If they are then treated with continuous intravenous epoprostenol, they will probably demonstrate improvement similar to the experience with children who are "nonresponders." Other novel therapeutic agents, discussed later, may also be considered for these patients.

## Targeted Pulmonary Arterial Hypertension Therapy

Prior to 1995, there were no approved therapies for PAH. However, since then, multiple randomized controlled trials with nine compounds as monotherapy have been completed in adult PAH patients. In addition, six randomized controlled trials evaluating combinations of agents (e.g., ET-receptor antagonists [ERAs] and PDE5 inhibitors, or prostacyclin analogues and ERAs or PDE5 inhibitors) have been completed. More than 5000 patients, the vast majority being adults, have participated in these studies aimed at developing effective treatments for PAH. The conclusions derived from clinical trials over the past 20 years have permitted development of an evidence-based treatment algorithm for adult patients with PAH.[14] However, despite there being multiple drugs currently approved for adults, until recently, none were approved for pediatric use. In September 2017, bosentan, an endothelin receptor antagonist, became the first drug to be FDA approved for use in children over 3 years of age diagnosed with idiopathic or congenital PAH. Based on similarities between pediatric and adult PAH, consensus recommendations for pediatric PAH have to date been extrapolated from adult data with off-label use in children. Although off-label use in pediatric patients appears to have significantly improved the overall quality of life and outcomes for many children with PAH, without adequate long-term safety studies and determination of optimal dosing, we may not be treating them optimally. Nevertheless, treatment for pediatric PAH currently uses the adult evidence-based guidelines. In 2015, the ATS/AHA pediatric pulmonary hypertension guidelines were published, outlining suggested pediatric dosages for medications used for PAH. The fifth World Symposium on Pulmonary Hypertension published a treatment algorithm based on risk stratification of PAH (Figs. 35.4 and 35.5).



AHA/ATS Consensus Pediatric PAH: Disease Severity

| LOWER RISK | DETERMINANTS OF RISK | HIGHER RISK |
|---|---|---|
| No | Clinical evidence of RV failure | Yes |
| I,II | WHO class | III,IV |
| None | Syncope | Recurrent syncope |
| Minimal RV enlargement/dysfunction | Echocardiography | Significant RV enlargement/dysfunction<br>Pericardial effusion |
| PVRI <10 WU × $m^2$<br>CI >3.0 L/min/$m^2$<br>PVR/SVR <0.5 | Hemodynamics | PVRI >20 WU × $m^2$<br>CI <2.0 L/min/$m^2$<br>PVR/SVR >1.0 |
| Minimally elevated | BNP/NTproBNP | Significantly elevated |
| Longer (>500 m) | 6MWD | Shorter (<300 m) |
| Peak $VO_2$ >25 mL/kg/min | CPET | Peak $VO_2$ <15 mL/kg/min |

Treatment of IPAH initially focused on the use of vasodilators in the hope that an increase in pulmonary vascular tone significantly contributed to the high PAPs. Although the bulk of the pulmonary vascular obstruction was clearly anatomic, vasodilators offered the prospect not only of decreasing PAPs somewhat, and therefore the hemodynamic burden on the right ventricle, but also of prompting reversibility of the anatomic lesions. Unfortunately, results from the use of vasodilators, which could affect the systemic as well as the pulmonary circulation, led to progressive disenchantment with one agent after another.

Less than 10% of adult IPAH patients and even fewer patients with PAH associated with other conditions such as CTD or CHD respond acutely to vasodilator testing and are candidates for calcium channel blockade. A landmark development for patients who failed to satisfy the criteria for a good hemodynamic response to acute vasodilator testing was the demonstration that such patients respond to continuous infusions of epoprostenol. That is, patients who fail to respond acutely to intravenous epoprostenol can respond chronically. Indeed, a substantial number of such patients have been treated this way for many years or have used continuous intravenous epoprostenol as a transition to transplantation or newer drug therapies. During this evolution, heart-lung and then lung transplantation became increasingly feasible and available, although the donor supply is still a significant limiting factor. Since 2002, the development of oral medications that block the receptors for ET or that augment the effects of endogenous NO by inhibiting PDE5 (the enzyme responsible for the inactivation of cyclic guanosine monophosphate) have been shown to be effective therapies and are extensively used. Alternative forms of delivery of longer-acting prostacyclin analogues, including subcutaneous and inhaled, are approved in adults and being used in children. They may delay the need for intravenous prostacyclin therapy in many patients.

As a result of these advances, a patient with PAH has several therapeutic options. However, none of these modalities are free from complications, and one must remember that all of these drugs were evaluated primarily in adult patients and not in children. Thus safety concerns for a class of drugs may be greater or less in children, based on their metabolism being different from adults. Many affected children are still growing, with ongoing lung development, and the optimal doses are not necessarily being used (or known). ET receptor antagonists can cause hepatic injury. The continuous infusion of a prostacyclin analogue has the risks associated with a permanently placed intravenous catheter, such as bacteremia, sepsis, or thromboembolic events. Transplantation offers the substitution of immunosuppression and its attendant risk of infection as a "better" or alternative option to RV failure. Despite the limitations of each of these therapeutic modalities, together they provide a graduated therapeutic approach that has provided, at each stage, a better quality of life for many children with PAH.

## Prostacyclin Analogues

### Intravenous Prostacyclin (Epoprostenol)

Epoprostenol (prostacyclin) has been used since its approval in 1995 with great success. It improves hemodynamics, quality of life, and exercise capacity in patients with IPAH and PAH associated with other conditions such as CHD, CTD, HIV infection, and portal hypertension, and increases survival in IPAH/HPAH. By the late 1990s, epoprostenol became the "gold" standard for treatment of IPAH in patients who were not responsive to acute vasodilator testing and therefore would not benefit from chronic oral calcium channel blockade. Epoprostenol (prostacyclin, prostaglandin $I_2$), a metabolite of arachidonic acid, and its analogues continue to be a major focus for treatment for a variety of forms of PAH. The pulmonary endothelium naturally elaborates prostacyclin into the bloodstream, where it has a short biological half-life (2–3 minutes). In principle, prostacyclin is attractive for the treatment of PAH on several accounts. It has been shown to (1) be a pulmonary vasodilator, (2) inhibit platelet aggregation, (3) inhibit proliferation of vascular smooth muscle, (4) improve endothelial dysfunction, and (5) possibly be a cardiac inotrope.

The use of prostacyclin or other prostacyclin analogues for the treatment of IPAH is supported by the demonstration of an imbalance in the TX to prostacyclin metabolites in patients with IPAH, as well as the demonstration of a reduction in prostacyclin synthase in the pulmonary arteries of patients with IPAH.[4,6,122] Although chronic intravenous epoprostenol improves exercise tolerance, hemodynamics, and survival in patients with IPAH, its mechanism(s) of action remains unclear. Epoprostenol lowers pulmonary artery pressure, increases cardiac output, and increases oxygen transport. These effects occur with long-term use, even if there is no acute response to vasodilator testing supporting the premise that epoprostenol has additional properties (other than as a pulmonary vasodilator), resulting in pulmonary vascular remodeling. The optimal dose of intravenous epoprostenol is unclear. The dose (ng/kg/min) is titrated incrementally, with the most rapid increases during the first several months of epoprostenol use. Although a mean dose at 1 year in adult patients is approximately 20–40 ng/kg/min, the mean dose at 1 year in children, particularly young children, is closer to 50–80 ng/kg/min, but there is significant patient variability in the "optimal" dose.[60]

Because epoprostenol is chemically unstable at neutral pH/room temperature and has a short half-life (1–2 minutes), chronic epoprostenol treatment requires a continuous intravenous delivery system with cold packs to maintain stability. A thermostable and PH stabilized molecule of epoprostenol is now available and is approved for use in adult PH. Permanent central venous access is required to administer the medication. Thus serious complications are associated with its use such as line sepsis, local site infection, and catheter dislodgment. In addition, pump malfunction may lead to a sudden bolus of epoprostenol (rare) or interruption of the medication that can cause severe rebound PAH. Therefore a search for alternate routes of drug delivery has led to the clinical development of oral, inhaled, and subcutaneous prostacyclin analogues. Treprostinil, a longer-acting prostacyclin analogue, is approved for continuous subcutaneous, continuous intravenous, or inhaled (administered four times daily) use, and can also be administered using a mini-pump that is more portable.

## Inhaled Prostacyclin Analogues (Iloprost, Treprostinil)

Iloprost, an inhaled prostacyclin analogue, may be advantageous because of the potential benefits of inhaled delivery that may avoid some of the systemic side effects, including hypotension, that can accompany epoprostenol use. Iloprost is a more stable synthetic analogue of prostacyclin.[123,124] It has a similar molecular structure to prostacyclin and acts through prostacyclin receptors on vascular endothelial cells. Iloprost has both vasodilator and platelet aggregation inhibition properties similar to prostacyclin. It has a biological half-life of approximately 20–25 minutes in humans, and it has been shown to have more pronounced short-term hemodynamic effects than iNO in patients with IPAH.

Inhaled iloprost (2.5–7.5 mcg, 6–9 times a day [median adult dose 30 μg/day]) was approved in 2004 for the treatment of PAH. The noninvasive delivery method makes it appealing, but the need for 6–9 treatments a day (each lasting 5–15 minutes) can be a considerable burden for patients, particularly children. Furthermore, the currently approved inhalation devices may be challenging for routine administration in young children. Randomized trials of inhaled iloprost versus intravenous epoprostenol are warranted, although the feasibility of such trials is problematic. It also has use in the intensive care setting where it has been used even more frequently (hourly and continuously) to prevent PH crises.

The acute effects of iNO have also been compared with aerosolized iloprost for children with pulmonary hypertension and congenital heart defects and found to be equally efficacious.[124,125] Although additive effects have been suggested when the two agents are used together, in this study there were no additive or synergistic effects.

In 2009 the prostacyclin analogue treprostinil was approved in its inhalation form for PAH. Based on a longer half-life than iloprost, inhaled treprostinil is given four times a day as opposed to six to nine times a day for inhaled iloprost. A two-institution case series described the safety and tolerability of this medication in the pediatric population.[126,127] The delivery system may be easier for younger children to administer effectively compared with inhaled iloprost.

## Subcutaneous/Intravenous Prostacyclin Analogue (Treprostinil)

Treprostinil sodium is a chemically stable prostacyclin analogue that shares at least some of the pharmacologic actions of epoprostenol. Acute hemodynamic effects with treprostinil are similar to those observed with intravenous epoprostenol in patients with IPAH; however, treprostinil is stable at room temperature and neutral pH and has a longer half-life, 2–3 hours, when administered subcutaneously. Similar to epoprostenol, treprostinil is infused continuously by a portable pump and can be administered either subcutaneously or intravenously. Treprostinil was approved in 2002 for subcutaneous infusion and in 2004 for intravenous infusion. The risk of central venous line infection is eliminated when treprostinil is used subcutaneously. Although no serious adverse events have been reported related to treprostinil or the delivery system when used subcutaneously, discomfort at the infusion site is common and may not be tolerated by older children.[126] There are recent literature describing use in infants and young children suggesting that the tolerability in this population is better than in older patients, indicating a difference in response to pain in infants with chronic lung disease of prematurity.[128–131]

## Oral Prostacyclin Analogues

### Oral Prostacyclin Analogue.

Oral treprostinil was approved for use in adults with PAH in 2013 and was found in trials to improve exercise capacity in PAH. This medication is associated with gastrointestinal side effects and headaches that are often dose limiting. Doses can begin with 0.125 mg or 0.25 mg twice a day with gradual increases as tolerated. No pediatric data are available for this medication. Oral selexipag, a prostacyclin receptor agonist, has also been studied and approved in adults with group 1 PAH, but there are currently no data on its use for pediatric PAH.[132] It was studied in the Prostacyclin (PGI2) Receptor Agonist In Pulmonary Arterial HypertensiON (GRIPHON) trial, a multicenter, double-blind, randomized, parallel-group, placebo-controlled, event-driven, phase III study which showed that among patients with PAH, the risk of the primary end point of death or PAH complication was significantly lower with selexipag as compared with placebo.[132–134] The adverse effects were similar to prostanoid therapy.

# Endothelin Receptor Antagonists

ET-1 is a potent mitogen and vasoconstrictor that is produced in excess by the hypertensive pulmonary endothelium.[70,135] Circulating levels of ET are increased in patients with PAH, and the magnitude of elevation correlates with survival. There are at least two different receptor subtypes: $ET_A$ receptors are localized on SMCs and mediate vasoconstriction and proliferation, whereas $ET_B$ receptors are found predominantly on endothelial cells and are associated with (1) endothelium-dependent vasorelaxation through the release of vasodilators (i.e., prostacyclin and NO), (2) clearance of ET, and (3) vasoconstriction (on SMCs) and bronchoconstriction. The use of ERAs, both dual receptor and selective $ET_A$ receptor antagonists, appears promising for children with PAH. For patients who do not have an acute response to vasodilator testing or have failed treatment with oral calcium channel blockade, ERAs may offer a viable treatment option. Bosentan, an orally active twice-daily dual $ET_A$ and $ET_B$ receptor antagonist, was approved in 2001 for adults with PAH and in September 2017 for children over 3 years of age with PAH.[50,136,137] This was a significant advance in the field of PAH in that prior to 2001 there were no oral therapies approved for PAH. This drug is generally well-tolerated; however, liver function must be monitored monthly because bosentan can produce significant hepatic dysfunction in approximately 8% of adult patients and approximately 3% of pediatric patients. In addition, because of potential teratogenicity, dual contraception is recommended, and care is advised while handling the medication by female caregivers. The FormUlation of bosenTan in pUlmonary arterial hypeRtEnsion (FUTURE)-2 study was an open-label long-term safety and tolerability phase III extension study of the FUTURE-1, which was a pharmacokinetic study of pediatric bosentan, showing that bosentan in a dose of 2 mg/kg twice a day was safe and effective.[138] A 5-year retrospective study of 101 children in the United Kingdom who received bosentan as monotherapy or combination showed that bosentan was safe and effective in slowing disease progression in pediatric PAH.[136,139]

Two selective oral $ET_A$ receptor antagonists, sitaxsentan and ambrisentan, have also been developed.[140] The rationale for selective $ET_A$ receptor blockade is that it may benefit patients by blocking the vasoconstrictor effects of the $ET_A$ receptor while maintaining the vasodilator and clearance effects of the $ET_B$ receptor. Sitaxentan was found to be associated with fatal hepatotoxicity and was withdrawn from commercial use in 2010. Ambrisentan is a longer-acting (once a day) selective $ET_A$ receptor blocker. The safety and tolerability of ambrisentan in the pediatric age group was described in a two institution case series, and the medication was shown to improve functional class and hemodynamics in a group of 38 pediatric patients.[141–143] Macitentan is a newer tissue-specific ERA that has been shown to reduce morbidity and mortality in patients with PAH in a multicenter, double-blind, randomized placebo controlled, event-driven phase III trial (Endothelin Receptor Antagonist in Pulmonary Arterial

Hypertension to Improve Clinical Outcome [SERAPHIN] trial).[144] This trial included patients older than 12 years. There are no studies describing the use of macitentan in patients younger than 12 years.

### Inhaled Nitric Oxide

NO is synthesized in endothelial cells from one of the guanidine nitrogens of L-arginine by the enzyme NO synthase. It has proved to be the endothelium-derived relaxing factor that contributes to the low initial tone of the pulmonary circulation. It has the advantage over other vasodilators of selectively relaxing pulmonary vessels without affecting systemic arterial pressure. It is currently being used as an acute test of vasoreactivity in a wide variety of pulmonary hypertensive states and is approved for PPHN.[145,146] When inhaled, the rapid combination of NO and hemoglobin inactivates any NO diffusing into the blood, preventing systemic vasodilatation. NO is therefore a potent and selective pulmonary vasodilator when administered by inhalation. NO may also have antiproliferative effects on smooth muscle and inhibit platelet adhesion. iNO has been demonstrated to be safe and efficacious in the treatment of PPHN. iNO has been useful for determining "operability" of patients with CHD. It has also been used for the treatment of IPAH exacerbations, perioperative pulmonary hypertension following cardiac surgery, and other forms of PAH. Clinical trials are in progress evaluating the safety and efficacy of chronic iNO in patients with inadequate responses to the currently approved PAH therapies.

## Phosphodiesterase Inhibitors

PDE5 inhibitors prevent the breakdown of cGMP, thereby raising cGMP levels. This effect should potentiate the pulmonary vasodilatation with NO. Sildenafil (orally active three times daily) and tadalafil (orally active once daily), both PDE5 inhibitors, enhance NO activity by inhibiting PDE5, the enzyme responsible for catabolism of cGMP. They were approved for the treatment of PAH in 2005 and 2009, respectively. PDE5 inhibitors may also be particularly beneficial in conjunction with chronic iNO, where withdrawal of NO may lead to rebound pulmonary hypertension.

Intravenous, long-acting oral, or aerosolized forms of PDE5 inhibitors all have therapeutic appeal. The effects of intravenous sildenafil were compared with iNO in preoperative and postoperative patients with CHD and elevated pulmonary vascular resistance.[147–149] In this study, intravenous sildenafil was as effective as iNO in children with CHD. The Sildenafil in Treatment-Naive Children, Aged 1-17 Years, With Pulmonary Arterial Hypertension (STARTS-1) trial was a multicenter, placebo-controlled double-blind study of low-, medium-, and high-dose oral sildenafil monotherapy in treatment naïve pediatric PAH.[150,151] Improvement in VO2, functional class, and hemodynamics were seen with medium- and high-dose sildenafil. The STARTS-2 extension study, done over 3 years, showed an increased signal of mortality in the higher dose range in IPAH but not in APAH-CHD, and there was a favorable survival for children on sildenafil across groups.[151] Based on these results, the European medicines agency approved sildenafil in children at a dose of 10 mg three times a day between 10 and 20 kg and 20 mg three times a day for >20 kg. The same data initially elicited a warning from the US Food and Drug Administration (FDA) in 2012, which was subsequently tempered down in 2014 to “judicious use by healthcare professionals when there is a favorable risk-benefit ratio for the patient” after publication of the STARTS 2 study and a review from the members of the pediatric pulmonary hypertension network.[152,153]

Tadalafil is a PDE5 inhibitor that is longer acting and suitable for once daily use. The initial experience describing its use in 33 children, either as a transition from sildenafil or initial therapy, suggested improved hemodynamics and functional class, with a similar side effect profile.[154] Larger studies are necessary to study the long-term effects of this drug in children.

The other available medication approved for adult PAH but have no reported pediatric experience is soluble guanylate cyclase stimulator riociguat, which is approved for WHO group 1 and 4 PH based on the randomized placebo-controlled phase III Pulmonary Arterial Hypertension Soluble Guanylate Cyclase–Stimulator Trial 1 (PATENT-1) and 2 (extension) and Chronic Thromboembolic Pulmonary Hypertension Soluble Guanylate Cyclase–Stimulator Trial 1 (CHEST-1) and 2 trials for PAH and inoperable CTEPH patients.[67,140,155]

## Gene Therapy

With the identification of an HPAH gene, a mutation in the BMPR2 protein at chromosomal locus 2q33 that is associated with FPAH in selected families, attention has focused on gene replacement therapy. An alternative therapeutic approach has been to induce the overexpression of vasodilator genes, notably endothelial NO synthase and prostacyclin synthase, because patients with various forms of PAH have been shown to have deficiencies in both. Given the preliminary clinical observations that exogenous administration of chronic NO or epoprostenol may have salutary effects on even advanced forms of the disease, it seems worthwhile to pursue these alternative modes of “drug delivery.” Advances in our understanding of the genetic predisposition associated with at least some, if not all, patients with PAH suggest that gene therapy may be possible in the future.

# Oxygen

Some patients who remain fully saturated while awake demonstrate modest systemic arterial oxygen desaturation with sleep, which appears to be due to mild hypoventilation. During these episodes, children with pulmonary hypertension may experience severe dyspnea, as well as syncope, with or without hypoxic seizures. Desaturation during sleep usually occurs during the early morning hours and can be eliminated by using supplemental oxygen. We recommend that children have supplemental oxygen available at home for emergency use. Children with PAH should be treated with supplemental oxygen during any significant upper respiratory tract infections if systemic arterial oxygen desaturation occurs. Children with desaturation due to right to left shunting through a patent foramen ovale usually do not improve their oxygen saturation with supplemental oxygen, although oxygen supplementation may reduce the degree of polycythemia in these children. A small study of children with ES demonstrated improved long-term survival with supplemental oxygen. However, in a subsequent study with 23 adult patients with ES, there was no significant improvement in survival with nocturnal oxygen. Some children experience arterial oxygen desaturation with exercise as a result of increased oxygen extraction in the face of fixed oxygen delivery and may benefit from ambulatory supplemental oxygen. In addition, children with severe right ventricular failure and resting hypoxemia, resulting from a markedly increased oxygen extraction, should also be treated with chronic supplemental oxygen therapy. Supplemental oxygen is also recommended for air travel to avoid alveolar hypoxia and exacerbation of the pulmonary hypertension.

## Additional Pharmacotherapy: Cardiac Glycosides, Diuretics, Antiarrhythmic Therapy, Inotropic Agents, and Nitrates

Although controversy persists regarding the value of digitalis in IPAH, children with right-sided heart failure may benefit from digitalis in addition to diuretic therapy. Diuretic therapy must be initiated cautiously because these patients are preload dependent to maintain optimal cardiac output. Despite this, relatively high doses of diuretic therapy are often needed. Although malignant arrhythmias are rare in pulmonary hypertension, treatment is appropriate for documented cases. Atrial flutter or fibrillation often precipitates an abrupt decrease in cardiac output and clinical deterioration due to loss of the atrial component. As opposed to healthy children, in whom atrial systole accounts for approximately 25% of the cardiac output, atrial systole in children with IPAH often contributes as much as 70% of the cardiac output. Therefore aggressive treatment of atrial flutter or fibrillation is advised.

Although there are no studies on the usefulness of intermittent or continuous treatment with inotropic agents, dobutamine can be used for additional inotropic support in conjunction with continuous intravenous epoprostenol in children with severe right ventricular dysfunction, as a bridge to transplantation. Children have also benefited from short-term inotropic support during acute pulmonary hypertensive crises to augment cardiac output during a period of increased metabolic demand.

Oral and sublingual nitrates have been used to treat chest pain in some children with IPAH, although the experience with these agents remains limited. Children who complain of chest tightness, or pressure, or vague discomfort that is responsive to sublingual nitroglycerin should be treated with chronic oral nitrates as well as sublingual nitroglycerin.

## Atrial Septostomy

Children with recurrent syncope in severe right heart failure have a very poor prognosis.[156] Exercise-induced syncope is due to systemic vasodilation, with an inability to augment cardiac output (through a fixed pulmonary vascular bed) to maintain adequate cerebral perfusion. If right to left shunting through an interatrial or interventricular communication is present, cardiac output can be maintained or increased if necessary. In addition, right to left shunting at the atrial level alleviates signs and symptoms of right heart failure by decompression of the right atrium and right ventricle. Increased survival has been reported in patients with IPAH with a patent foramen ovale, although this remains controversial. Patency of the foramen ovale may improve survival if it allows sufficient right to left shunting to maintain cardiac output. Successful palliation of symptoms with atrial septostomy has been reported in several series.[157–159] In our experience, patients with PAH with recurrent syncope or right heart failure improve clinically, as well as hemodynamically, following atrial septostomy: patients experience no further syncope, and signs and symptoms of right-sided heart failure improve. Although systemic arterial oxygen saturation decreases, overall cardiac output and oxygen delivery improve, despite the right to left shunting at the atrial level. In our experience, atrial septostomy results in a survival benefit; the survival rates at 1 and 2 years are 87% and 76%, respectively, compared with conventional therapy (64% and 42% at 1 and 2 years, respectively).[158,159] Thus, although atrial septostomy does not alter the underlying disease process, it may improve quality of life and represent an alternative for selected patients with severe IPAH. However, this invasive procedure is not without risk; our indications for the procedure include recurrent syncope or right ventricular failure despite maximal medical therapy, and as a bridge to transplantation. Closure of the atrial septal defect can be performed at the time of transplantation.

### Potts Shunt in Severe Pulmonary Arterial Hypertension

Until the past decade, balloon atrial septostomy and lung transplant were the only available options for severe refractory pulmonary hypertension with heart failure. Because of better prognosis in Eisenmenger patients with great artery level shunts, the Potts shunt was proposed as an attractive alternative. The physiologic advantage is sparing the cerebral and coronary circulation of desaturated blood (as with an atrial septostomy) and also a more effective decompression of the hypertensive RV through the creation of a descending aorta-left pulmonary anastomosis. Baruteau et al. reported their experience in 24 children who underwent a Potts shunt over an 11-year period, of which five were done transcatheter. There were three early surgical deaths, but in the 21 of 24 survivors, there was dramatic improvement in functional class to 1 or 2, normalization of BNP, weaning off prostanoids, and catch up in growth. To prevent left to right shunting through the shunt and flooding of the lungs, this group also developed a unidirectional valved shunt, which would act as a pop-off only during suprasystemic right-sided pressures, without flooding the lungs.[160–163]

## Lung Transplantation

Although successful heart-lung transplantation, as well as single and double lung transplantation with repair of congenital heart defect(s), has been available for more than 20 years, there are several limitations to these procedures. A limited number of centers perform the procedures in children, and the availability of suitable donors is limited. Furthermore, the high incidence of chronic allograft rejection or bronchiolitis obliterans in the transplanted organs of these patients (25%–50%) and the potential consequences of life-long immunosuppression are of great concern. Both single and bilateral lung transplantation have been performed in pediatric patients with pulmonary vascular obstructive disease, including patients with severe right ventricular failure.[164] Currently, the overall 1-, 5-, and 10-year survival following lung transplantation for PAH patients is 64%, 44%, and 20%, respectively. There has been no significant improvement in survival in more recent years (e.g., 1998–2001 versus 1992–1998). For untreated Eisenmenger patients, the natural history is much more favorable. The 5- and 25-year survival is greater than 80% and 40%, respectively, for untreated Eisenmenger patients, as opposed to following lung transplantation with a 1- and 5-year survival of 52% and 39%, respectively. Thus transplantation is most often reserved for WHO functional class III and IV patients with PAH who have progressed despite optimal medical therapy (see Box 35.2). As progress is made in the medical management of PAH, the indications for transplantation will change. The course of the disease and the waiting time must be taken into account when referring for transplantation. Ideally, children should be listed when their probability of 2-year survival without transplantation is 50% or less. Although there are advantages and disadvantages to each operation (i.e., lung [single or double] versus heart-lung transplantation), there is currently no consensus regarding the optimal procedure. The availability of donor organs often influences the choice of procedure. It is possible that data on long-term survival will demonstrate a survival advantage of one procedure over another. Although lung and heart/lung transplantation are imperfect therapies for PAH, when offered to appropriately selected patients, transplantation may improve survival with an improved quality of life. Early referral to a center with expertise in pediatric lung and heart-lung transplantation will decrease pretransplantation mortality and allow families to have adequate time to make an informed and thoughtful choice about this therapy. Living-related donor transplantation remains controversial; although it has been successful, there is limited experience.

## Conclusions

Recent therapeutic advances have significantly improved the prognosis for children with PAH. Nevertheless, PAH remains a serious condition that is extremely challenging to manage. Chronic vasodilator therapy with calcium channel blockade in "acute responders" to vasodilator testing, and continuous intravenous epoprostenol in "nonresponders" appears to be effective in children, with observational studies reporting improved survival, hemodynamics, and symptoms. In addition, prostacyclin analogues administered by inhalation, continuous subcutaneous or continuous intravenous infusion, or oral ERAs and oral PDE5 inhibitors are available for the treatment of PAH. Although not approved for PAH, iNO is frequently used in the acute setting, with chronic administration undergoing evaluation. In a carefully controlled setting, there may be a role for transitioning PAH children who have had an excellent response to long-term intravenous epoprostenol therapy to oral or inhaled agents. In the future, there will undoubtedly be more treatment options for patients with PAH. However, in the early stages of use and without controlled studies for comparison, the newer agents should be used cautiously with close monitoring for treatment failure. Based on distinct mechanism(s) of action, combination therapy may further improve the overall efficacy of treating a child's PAH. Future developments in vascular biology will improve our understanding of the etiologies of PAH and its pathobiology, as well as provide rationale for more specific medical therapies. The current treatment algorithm for pediatric patients, extrapolated from adult evidence-based guidelines, will continue to evolve as newer agents become available (see Fig. 35.5). Whether these new agents will prove to be as effective as intravenous epoprostenol in selected children remains unknown. In addition, with increasing collaborative efforts between pharmaceutical companies, regulatory agencies, and academia, the future of clinical drug development for pediatric patients looks bright. Such studies should further the advances made to date in treating children with PAH, as even when the disease is similar between children and adults, children are not merely "small adults." Optimal care for pediatric patients requires knowledge of the therapies assessed in pediatric patients in addition to study in adult patients.

We hope that by increasing our understanding of the pathobiology of PAH, novel treatment strategies will continue to evolve and one day we will be able to prevent and cure this disease.

# Pulmonary Edema

*Hugh O'Brodovich MD*

Improvements in the intensive care and monitoring of patients with serious illnesses led to a greater appreciation of the significance of fluid movement into the lung as a complication of a variety of conditions. This, coupled with an improved understanding of the pathogenesis of pulmonary edema, has enhanced our ability to treat various illnesses in which pulmonary edema develops.

The chapter first outlines the relevant anatomy, factors that control fluid movement within the lung, mechanisms responsible for the genesis of pulmonary edema, and how this edema fluid is cleared from the lung's interstitium and airspaces. This background will enhance the reader's understanding of the pathophysiologic consequences of edema formation, including the clinical and laboratory findings. Common disorders associated with pulmonary edema are then described along with the approach to therapy, which is based on understanding the underlying pathophysiologic mechanisms.

## Anatomic Considerations

Certain structural features of the lung are worth pointing out because they have a bearing on gas exchange during pulmonary edema. The capillaries are placed eccentrically within the alveolar septum (Fig. 36.1A). In some areas, the basement membranes of the capillary endothelium and the alveolar epithelium are fused with no additional space between them, even during edema formation.

This situation is ideal for preserving gas exchange, at least until such time as the alveoli themselves are filled with liquid. In other areas, there is an interstitial space between the endothelial and epithelial basement membranes that contains secreted matrix. This matrix consists of structural proteins (e.g., collagens and elastin), attachment proteins for cells (e.g., laminin), and proteoglycans and glycosaminoglycans (e.g., hyaluronic acid, chondroitins, and heparan sulfate). In addition to supplying support to the capillary network, this widened portion of the alveolar-capillary membrane provides a channel for water and protein *en route* to the lymphatics and larger interstitial fluid spaces (see Fig. 36.1B). As long as fluid can be confined to these channels, gas exchange can be preserved. Morphometric studies have shown that the majority of interstitial edema accumulates within the thick, and not the thin, portion of the alveolar-capillary membrane.[1]

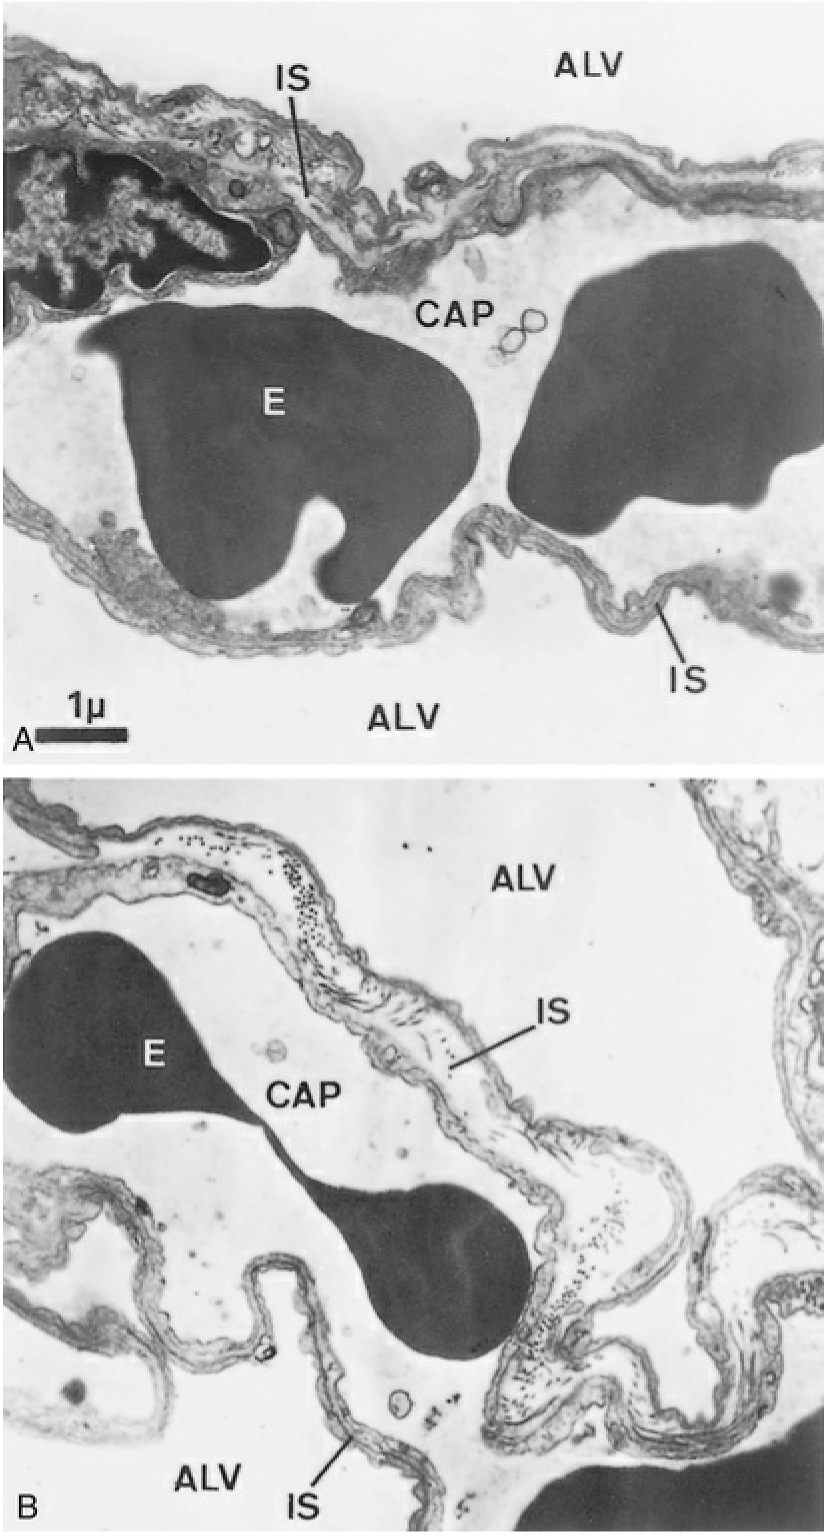

**FIG. 36.1** (A) The normal alveolar septum in which the epithelial and endothelial basement membranes are fused in some areas and separated by an interstitial space of connective tissue in others. (B) The alveolar septum in pulmonary edema. The areas where the basement membranes are fused remain thin; only the areas with a connective tissue interstitial space widen.

Pulmonary capillaries, similar to muscle capillaries, have a continuous endothelium with relatively tight intercellular junctions. The bronchial microvasculature, much like visceral capillaries, is discontinuous, with intercellular fenestrations or gaps. Whether these gaps account for the greater fluid movement across the bronchial capillaries, but not the pulmonary capillaries, remains to be determined. The role of bronchial circulation in the genesis of pulmonary edema may have been underestimated, but it is certain that bronchial circulation plays an important pathophysiologic role in inflammatory airway diseases such as asthma and inhalational lung injury.

At the ultrastructural level, the available evidence from tracer studies indicates that the alveolar epithelial membrane contains tighter intercellular junctions than does the capillary endothelial membrane. These epithelial tight junctions (zonulae occludentes) are estimated by both morphologic and physiologic studies to have an effective molecular radius of approximately 4 Å. This has two implications. First, they markedly restrict the movement of small ions, thereby making ions the most important solute in the genesis of osmotic pressure across the epithelial membrane. Second, fluid leaking from the vascular spaces is likely to be confined initially to the interstitial and lymphatic spaces; alveolar edema results only when the volume that can be handled by these spaces is overwhelmed. In contrast to the epithelium, the pores between endothelial cells have an effective molecular radius of approximately 40 Å. This 10-fold difference in interendothelial junction size allows the free movement of small ions and noncharged solutes, such as urea, but restricts the movement of larger macromolecules such as albumin and globulins. Thus, it is the protein concentration that is the most important solute in the genesis of transvascular osmotic pressure. These large macromolecules move across the microvasculature; however, the relative contributions of movement via pinocytotic vesicles (vesicular shuttle) versus across pores that can enlarge (“stretched pores”), especially when there is increased intravascular pressure or injury, is unclear.

Although the alveoli are often portrayed as spherical, a polyhedral model is closer to reality (see Chapter 6). From the perspective of fluid movement in the lung, the importance of this shape is that the walls of the alveolar septa are flat, except at the corners where the septa meet. Thus, it is only at the corners, where the alveolar air-liquid interface is curved, that the force exerted by surface tension can lower alveolar fluid and interstitial fluid pressures as predicted by the LaPlace relationship. The lower interstitial pressures at the corners favor movement of interstitial fluid that has traversed the alveolar capillary wall toward the corners of the alveolus. This is important from a lung fluid balance perspective. Alveolar type II epithelial cells are also predominately found in the corners of the alveoli.

Pulmonary blood vessels have been defined using both anatomic and physiologic criteria (see Chapter 6). Anatomically, the vessels have been classified traditionally by their morphologic characteristics as arteries, arterioles, capillaries, venules, or veins. Physiologically, these divisions are included under two broad classifications—alveolar and extraalveolar vessels—based on their behavior relative to the hydrostatic pressures of the interstitium surrounding the vessels, the interstitial fluid pressure. Alveolar vessels are in the alveolar walls and behave as if their outer walls were exposed to alveolar pressure. These vessels may collapse if airway pressures exceed vascular pressures, as is the case in zone I perfusion conditions. Extraalveolar vessels lie in the larger interstitial spaces and behave as if their outer walls were exposed to a pressure that is as negative as or more negative than pleural pressure and that tends to vary with pleural pressure. In addition, there are vessels lying in the intersections of alveolar septal walls (corner vessels) that are exposed to more negative pressures than the alveolar vessels. Unfortunately, there is no clear-cut correlation between the functional and the anatomic classifications. Fluid movement occurs at the level of the arterioles, capillaries, and venules; the bulk of fluid movement occurs at the level of the capillaries, with approximately three-fourths arising from the alveolar vessels.[2]

Anatomically, the lung has two main compartments, each possessing markedly different potential volumes, into which edema fluid can move. The interstitial spaces of the alveolar capillary septae and peribronchovascular compartment can only accommodate small amounts of fluid. When this small interstitial safety reservoir, estimated to be a few hundred milliliters in an adult lung,[3] is filled with edema fluid, subsequent accumulation must take place in the alveolar space, which at functional residual capacity (FRC) has a volume of approximately 30–40 mL/kg body weight or approximately 2000–3000 mL in the adult lung. This anatomic difference, in part, explains why interstitial edema may resolve quickly, whereas alveolar edema takes significantly longer periods of time.

Juxtacapillary (J) receptors are distributed throughout the lung's interstitium and are stimulated by the presence of edema. They induce an increase in respiratory rate and their continued activation is responsible, in large part, for the continued tachypnea seen in pulmonary edema even when hypoxemia has been corrected through the use of supplemental oxygen and positive airway pressure.

## Factors Responsible for Fluid Movement

The factors responsible for fluid accumulation include intravascular and interstitial hydrostatic and colloid osmotic pressures, permeability characteristics of the fluid-exchanging membrane, and lymphatic drainage.

The equilibrium of fluid across fluid-exchanging membranes is generally expressed as the Starling equation:

$$Q_f = K_f[(Pmv - Ppmv) - \sigma(\pi mv - \pi pmv)]$$

wherein, $Q_f$ = the net transvascular flow; $K_f$ = the hydraulic conductivity and filtration surface area of the fluid-exchanging vessels; $Pmv$ = microvascular hydrostatic pressure; $Ppmv$ = perimicrovascular (interstitial fluid) hydrostatic pressure; $\pi mv$ =

colloid osmotic pressure in the microvasculature; $\pi pmv$ = colloid osmotic pressure in the perimicrovasculature, the interstitial fluid colloid osmotic pressure; and $\sigma$ = the reflection coefficient, which is a measure of the resistance of the membrane to the movement of protein. Thus, $\sigma$ influences the "effective" osmotic pressure of the protein. If the endothelium were completely impermeable to protein ($\sigma_{\text{protein}} = 1$), then the 5 g/dL of plasma would yield approximately 28 mm Hg osmotic pressure (each 1 mOsm/L of solute yields 19 mm Hg pressure). The osmotic pressure resulting from proteins is also termed the "oncotic pressure."

As discussed subsequently, the absolute values for the variables within the Starling equation may change during health and disease. However, it should be emphasized that in the normal lung, $Q_f$ is positive and there is a continuous movement of fluid from the vascular to the interstitial spaces of the lung. Experimentally derived values are approximately: $Pmv$ = 20 cm $H_2O$, $Ppmv$ = −2 cm $H_2O$, $\pi mv$ = −33 cm $H_2O$, $\pi pmv$ = 20 cm $H_2O$, and $0.7 < \sigma < 0.95$.

The term *microvasculature* is used to describe the vessels from which fluid leaks because fluid exchange is not limited to the capillaries alone. In the following discussion, each of the above factors and the pathophysiologic influences on them are described in detail.

## Vascular Forces

The pressure in the pulmonary microvasculature (Pmv) is frequently, but not precisely, referred to as pulmonary capillary pressure. For technical reasons, this pressure is extremely difficult to measure *in vivo.* The pulmonary artery wedge pressure (Pw), also known as the pulmonary artery occlusion pressure, reflects the pressure in the first pulmonary veins where there is flow from nonobstructed vascular routes. Pmv is higher than left atrial (LA) pressure by approximately 40% of the difference between LA pressure and pulmonary arterial (PA) pressure. The relative amounts of arterial and venular resistance within the pulmonary vasculature is altered during hypoxia, the infusion of vasoactive agents (e.g., catecholamines) or during disease (e.g., endotoxinemia). An increase in either PA or LA pressure will tend to increase the hydrostatic pressure, favoring movement out of the fluid-exchanging vessels. For example, Pmv may be increased by the elevation in LA pressures in left-sided heart failure or by increases in PA pressure as seen in large left-to-right shunts. Although both PA and Pw pressures increase in a linear relation to exercise-induced increases in cardiac output, the ratio is significantly less than 1 : 1 in healthy young adult humans.[4] Because the pulmonary vascular membrane is only slightly permeable to proteins and freely permeable to ions and small uncharged solutes, the plasma proteins normally are responsible for osmotic pressure ($\pi$mv). The $\pi$mv is significantly above the pulmonary microvascular hydrostatic pressure. The plasma colloid osmotic pressure may be markedly reduced in clinical conditions in which the plasma proteins are low (e.g., malnutrition, nephrosis, and massive burns) and thus may facilitate the formation of pulmonary edema.

## Interstitial Forces

The interstitial hydrostatic pressure throughout the lung is normally negative relative to alveolar pressure,[5] and there is a positive alveolar-hilar pressure gradient[6] that facilitates the movement of interstitial fluid from alveolar to perihilar interstitial areas. The pressure surrounding the corner and extraalveolar vessels is less than pleural pressure[5] and becomes considerably more negative at high lung volumes. In disease, these negative pressures may be amplified many fold because of “mechanical interdependence” of lung units.[7] When the expansion of some units of the lung lags behind surrounding lung units because of disease, the force per unit area distending the lagging unit is increased. Amplification of transpulmonary (distending) pressures by mechanical interdependence is seen in conditions characterized by increased respiratory resistance, decreased lung compliance, and expansion of the lung from the airless state. Mechanical interdependence can act on diseased areas of the lung to produce distending pressures that are exceedingly high. When transmitted to the interstitial space around blood vessels, these pressures can enhance edema formation and can cause the rupture of vessels.

These considerations become especially important, because various forms of constant distending pressures are used therapeutically. Although only 5–10 cm $H_2O$ may be applied, if the pressure does not distend some areas of the lung as quickly as others, the pressure surrounding lagging units may be considerably greater because of amplification.

Surfactant alters the liquid pressure within the airspace and, by extrapolation, the alveolar interstitial pressure.[8] Thus increased air-liquid surface tension, whether as a result of inadequate or dysfunctional surfactant, will promote the movement of fluid from the vessels into the lungs.

## Microvascular Filtration Coefficient and Vascular Permeability

There are significant technical difficulties in obtaining an accurate estimate of the $K_f$ within intact lungs and, dependent upon the species and experimental approach, estimates had varied by more than three orders of magnitude. However, when the experimental protocol ensures that there is full recruitment of the pulmonary vascular surface area, there is remarkable consistency of the normalized baseline $K_f$ values between species with widely varying body weights from mice to sheep.[9] Because there is a similar relation between alveolar surface area and body mass of different species, this feature optimizes gas exchange.

Experiments have shown that the walls of the pulmonary circulation are not a perfect semipermeable membrane and that the normal pulmonary vasculature has $0 < \sigma < 1$. The endothelial membrane has “pores” that are larger than some protein molecules. Fluid filtering through a pore will drag some protein with it. The larger the protein relative to the size of the pore, the less protein will be dragged. When the protein is the same size as or larger than the pore, the reflection coefficient $\sigma$ is 1. As the size of the protein becomes progressively smaller, $\sigma$ approaches zero.[10]

Early experimental evidence suggested that the microvascular permeability to protein is greater in the young than in the adult animal; however, subsequent work showed that there was no difference in lung microvascular permeability to protein between late-term and postnatal animals and that the higher rate of fluid movement out of the newborn lung's microvasculature bed likely results from a greater portion of the younger smaller lung being in West's zone III perfusion status.[11]

## Lymphatic Clearance

Whether there is fluid accumulation in the lung depends on the balance between fluid filtration into the lung and lymphatic clearance. Early in the onset of interstitial edema, lymphatic drainage of fluid is an important protective mechanism to prevent alveolar flooding. Although early work had indicated that increased motion or ventilation of the lung increased the lymphatic fluid drainage, suggesting a passive milking action, it is now known that there are active contractions of the lymphatic smooth muscle that can be further augmented by vasoactive agents. Indeed, rhythmic inflation and deflation is not required for normal lymphatic function in lungs that have normal or increased vascular permeability.[12] Lung lymph flow can increase up to tenfold acutely, and when there is chronic edema, the maximal ability of the lymphatics to clear fluid may increase many fold, presumably as the result of proliferation of the lymphatic vasculature. Because the lymphatics ultimately drain into the great veins, elevation of systemic venous pressure might be expected to increase fluid accumulation, not only by raising pressure in the fluid-exchanging vessels, but also by opposing lymphatic drainage.

## Surface Tension

Surface tension at the air-liquid interface on the inner surface of the alveolus tends to pull fluid away from the alveolar epithelium with a force of at least 2 mm Hg. This surface tension at the alveolar air-liquid interface would be expected to expand the perivascular space and to lower perimicrovascular pressure. As pulmonary edema fluid enters the airspace, it first collects in the corners, but as fluid continues to accumulate, the filling of an alveolus with fluid is self-accelerating once there is a critical amount of fluid present.

### Safety Factors That Oppose Edema Formation

A variety of clinical observations have indicated that transvascular hydrostatic pressures must be raised by 15–20 mm Hg before edema develops. Several factors provide this protection against edema formation. The interstitial fluid pressure, as previously described, is below alveolar pressure[13] and will rise when there is even minimal amounts of fluid accumulation within the lung[5,6] and thus oppose fluid movement. At the same time, the filtered fluid will dilute the interstitial plasma protein, thus lowering the interstitial colloid osmotic pressure and diminishing the movement of fluid out of the microvasculature. Lymphatic drainage of fluid and protein also contributes to this "margin of safety." The interstitial space itself, especially around the bronchi and blood vessels (bronchovascular cuffs), can sequester fluid (several hundred milliliters in the adult) and thus can provide an additional safety factor before fluid floods the alveoli.

## Mechanisms That Cause Pulmonary Edema

There has been much effort to classify the different causes of pulmonary edema into cardiogenic and noncardiogenic pulmonary edema. Although this is useful to some degree, it should be remembered that in many lung diseases characterized by pulmonary edema, there are both increased transvascular pressure gradients and increased permeability to solutes. For example, 30% of patients diagnosed with acute lung injury (ALI) have a pulmonary artery wedge (occlusion) pressure greater than 18 mm Hg.[14] The various etiologies of pulmonary edema are introduced by using the Starling equation as the basis for the discussion.

### Increased Hydrostatic Pressure in the Pulmonary Microvasculature

Increased hydrostatic pressure in the Pmv is the most common and perhaps most easily understood cause of pulmonary edema in the pediatric and adult population. A variety of clinical conditions are associated with increased hydrostatic pressures in the Pmv, either as the result of elevation of vascular pressures distal to the lung's parenchyma, increased blood flow, increased blood volume, or PA or venular hypertension. In each case, there would be an increase in the amount of water and solute leaving the microvasculature and entering the interstitium. Although hypoxia increases PA pressures, it does not by itself increase vascular permeability to solutes.[15]

## Decreased Plasma Colloid Osmotic Pressure

If a patient has no other disorders, hypoproteinemia will not, by itself, cause pulmonary edema. Large pleural effusions may develop in diseases such as the nephrotic syndrome, but there is no evidence of lung edema as assessed by gas exchange and chest radiography. However, in patients where vascular pressure or alveolar capillary membrane permeability increases, pulmonary edema is more likely to develop and be more severe when the plasma protein concentration is low. This is seen in various conditions including severe malnutrition, massive burns, protein-losing enteropathies, and nephrosis. Hypoproteinemia also can be seen in patients with a variety of other conditions when withdrawal of multiple blood samples for diagnostic purposes is coupled with the administration of large amounts of noncolloid-containing fluids.

## Decreased Interstitial Hydrostatic Pressure
